For this reason, permafrost-affected soils in Boreal and Subarctic regions are highly sensitive to disturbance, and fire is an important factor in controlling soil properties and vegetation patterns. The Boreal forest burns and is subject to frequent lightning-ignited fires during the summer. In soils recently affected by fire, vegetation is commonly altered to willow (*Salix* sp. L.) shrub and aspen (*Populus* sp. L.) or mixed white spruce–aspen forest. While pH in the uppermost organic layers of Boreal and Subarctic soils is typically acidic, following fire it can increase to near-neutral or slightly alkaline due to the concentration of base cations released from the combusted organic materials. These pH values typically decline as the organic layer regrows and re-acidifies. Combustion and consolidation of the insulating surface organic materials can warm underlying soils, and where there is near-surface permafrost it can lower the permafrost table. Under ‘stable’ climatic conditions, soil and ecosystem recovery occurs over centuries, with return to pre-burn conditions as the surface organic layers recover and the permafrost table aggrades.

Fig. 1 Pedological zonation, permafrost extent, and soil temperature regimes of the Northern Circumpolar region. (A) Pedological zones are re-interpreted from [Tedrow \(1977\)](#) and [Ugolini \(1986\)](#) with addition of the spatial distribution of Arctic bioclimate Subzones from the Circumpolar Arctic Vegetation Map (CAVM) project ([Walker et al., 2005](#)). The distribution of polar desert (a portion of the High Arctic) corresponds with Arctic bioclimate subzone A, while the rest of the High Arctic includes bioclimate subzones B and C. The Low Arctic includes CAVM bioclimate subzones D and E. The Subarctic–Boreal boundary is interpreted from [Ugolini \(1986\)](#). The southernmost extent of the Boreal zone is interpreted with the southern Boreal boundary from the Boreal Forest monitoring project data ([Potapov et al., 2008](#)). (B) Permafrost zonation is from the Circum-Arctic Map of Permafrost and Ground-Ice Conditions ([Brown et al., 2002](#)). (C) Soil temperature regime data are from [USDA-NRCS. \(2016\)](#).

Jelinski); (B) Subarctic landscape on the southern flanks of the Brooks Range, Alaska, USA, N.A. Jelinski); (C) Spodosol (Podzol) formed in glacial outwash, Walker Lake, Alaska (N.A. Jelinski), (D) Dystricryept (Cambisol) formed in loess over residuum, Fairbanks Area, Alaska (N.A. Jelinski), (E) Hemist (Histosol) over glaciolacustrine sediments in northern Minnesota, USA (N.A. Jelinski), (F) Histoturbel (Cryosol), formed in glaciolacustrine sediments, Copper River Basin, Alaska (N.A. Jelinski).

- *Soil formation.* In upland soils of the southern and maritime influenced regions of the Boreal and Subarctic, temperatures are warm and infiltration intense in well drained soils without permafrost. Pedogenesis is largely controlled by excess moisture and free drainage, resulting in the leaching (eluviation) and downward movement (illuviation) of dissolved organic matter and iron oxy-hydroxides (podzolization), fine clays (argilluviation), and carbonates (decalcification). These processes are similar to those in northern parts of the humid temperate zone, except for the more intense seasonal freeze–thaw cycles in cold regions (Fig. 2). The most common mechanism of soil formation in well-drained coarse-textured parent materials is podzolization, caused by the action of weak acids from acidic litter. Podzolization is common in the Boreal where rainfall exceeds 500 to 700 mm year⁻¹. Argilluviation is rare in the Subarctic and sporadic in the Boreal, whereas it dominates soil development in humid temperate regions. Finally, iron oxidation and acidification in upper soil horizons leads to brunification, resulting in well developed, oxidized upper soil horizons.

The differences between soil properties on opposing aspects of the same hillslope in the Boreal and Subarctic can be quite dramatic and are amplified with increasing slope due to major differences in effective solar radiation, which affects seasonal moisture balance and soil temperature. For example, in Subarctic Interior Alaska, acidic soils with near-surface permafrost and thick surface organic materials are common on northeast facing slopes which receive little direct solar radiation during the growing season. In contrast, on southwest facing slopes receiving greater solar radiation, warmer, drier soils develop, with thin surface organic materials and carbonates higher in the soil profile.

In poorly drained lowlands of the Subarctic and Boreal landscape, soils have developed under forested or non-forested wetlands dominated by sedges (*Carex* sp. L.), mosses and lichens. The combination of cold temperatures and anaerobic conditions in these wetlands can result in the accumulation of a thick deposits of organic materials (Fig. 2). The peatlands of the Boreal and Subarctic lowland regions of Canada and western Siberian Lowlands (the Hudson Bay Lowlands and the Ob and Yenisei Lowlands) and the Kolyma Lowland of eastern Siberia hold some of the largest carbon stocks of any soils in the world (Hugelius et al., 2020).

Saturation and iron reduction (gleization) is a major soil forming process in poorly drained soils (which includes both lowland soils and permafrost-affected upland soils). Many soils in the Boreal and Subarctic, particularly those with near-surface permafrost, undergo gleization due to long-term saturation and iron reduction at some depth. In addition, seasonal gleization closer to the soil surface can also occur in pockets in otherwise oxidized upland soil, when, during snowmelt, seasonal frost or permafrost does not enable downward percolation of excess water and the upper soil remains saturated for some time.

Cryoturbation occurs in Boreal and Subarctic soils, but typically only in those with near-surface permafrost, and at a lower intensity than in the Low and High Arctic (Ping et al., 2008a; Jelinski et al., 2019). Where patterned ground does occur it is often dominated by vegetated earth hummocks that can often be relict (Walker et al., 2005; Ping et al., 2008a,b). Frost cracking does not play a major role in the Boreal and Subarctic due to warmer temperatures, greater rainfall, and well vegetated protected surfaces. Because frost cracking is less intense than at higher latitudes, lenticular cryostructures from ice lens formation are the predominant cryostructures (Jelinski et al., 2019).

- **Classification and carbon stocks.** Soils of the Boreal and Subarctic are dominated by Inceptisols (Cambisols) and Gelisols (Cryosols), which cover approximately two thirds of the ice-free land area (36% and 32%, respectively). Spodosols (Podzols) are the next most prevalent soil order (15%), followed by Alfisols (Luvisols/Albeluvisols) in the southern Boreal (5%), and Histosols (Histosols) (~4%), with minor components of Entisols (Regosols), Mollisols (Chernozems) and Andisols (Andosols). Although Andisols comprise a minor component of Boreal and Subarctic regions, they can be the dominant soils along the Pacific 'ring of fire' in the Boreal zone. Carbon stocks (to 1-m depth) in the Boreal and Subarctic can be high, ranging from 10 kg C m⁻² in well-drained mineral soils to >100 kg C m⁻² in poorly drained peatlands (Hugelius et al., 2020).

Low Arctic regions

Low Arctic soils are associated with gelic and pergelic MASTs and have continuous near-surface permafrost across more than 90% of the landscape. The treeline which marks the boundary between the Subarctic at the northern edge of forested regions and the Low Arctic is one of the most striking vegetative transitions on Earth. With colder temperatures and decreased precipitation, chemical weathering and biochemical processes are generally less intensive in the Low Arctic than in the Boreal and Subarctic.

- **Climate.** Much of the Low Arctic lies close to the Arctic Ocean and lacks the major climatic distinctions between continental and maritime regions which occur in the Subarctic and Boreal. Summer high temperatures average < 10 to 15 °C, while winter highs are typically -10 to -20 °C. In the Low Arctic, approximately 50 to 75% of the total precipitation occurs as rain during the growing season. Rainfall ranges from 100 to 250 mm year⁻¹, with an additional 50–150 mm of water equivalent as snow. Although precipitation is less than in the Subarctic and Boreal, poorly drained soils dominate the Low Arctic because of ubiquitous near-surface permafrost, which acts as an aquitard leading to a perched water table (Ping et al., 2008a,b). This, together with low annual rates of evapotranspiration, results in predominantly hydric conditions in Low Arctic soils (Tedrow, 1977).
- **Vegetation.** Soils with near-surface permafrost and in lowlands of the Low Arctic are characterized by wet cotton grass and sedge meadows, dominated by *Carex* sp., *Eriophorum* sp., and *Kobresia* sp. Closed to open canopy low (40 cm to >2 m) and dwarf (< 40 cm) shrub tundra, (dominated by *Betula* sp., *Salix* sp. and *Alnus* sp.) occupies much of the remaining landscape (Walker et al., 2005). Vegetative cover in most non-mountainous areas of the Low Arctic is almost continuous, and all soils have surface organic horizons of varying thickness. The major exception to continuity of vegetation cover is bare soil associated with patterned ground features. Fire disturbance does occur naturally and has an effect on ecosystem structure and function, but it is not common and return intervals are much longer than in the Boreal and Subarctic.
- **Soil formation.** Decomposition of organic materials (melanization, humification, mineralization) in Low Arctic soils is significantly slower than at lower latitudes because of colder and wetter conditions. There is widespread accumulation of organic matter (paludification), however due to the absence of acidic needleleaf litter and less intense eluviation, acidification does not occur as deeply as in the Subarctic and Boreal. The Low Arctic includes large areas of acidic, permafrost-affected peatland soils (Fig. 3), but on the coastal plains, fens dominate and the soils can be slightly to moderately alkaline (Ping et al., 2008a,b). On lower hillslope positions (footslopes, toeslopes, and basins), ice content and the accumulation of organic materials can increase markedly, with organic materials reaching several meters in thickness. Permafrost-affected mineral soil materials across much of the landscape show morphological characteristics of saturation and iron reduction (gleization). The near-surface pH values of wet mineral soils in the Low Arctic are 4.5–6.5, but, where there is carbonate-rich loess cover, the soils are alkaline (Ping et al., 2005, 2008a,b).

There are also smaller areas of well-drained soils in the Low Arctic. These soils typically form on upper hillslope positions of broad glacial moraines and develop on sites where there is free drainage to a depth of at least 60 cm or soils shallow to bedrock. They are characterized by oxidized, brownish colors in the upper solum, similar to upland soils of the Subarctic and Boreal. Well-drained soils can also be found in bare spots on patterned ground where the mineral soil is exposed at the surface.

Low Arctic soils are commonly characterized by patterned ground and cryoturbation. Ice wedge polygons and non-sorted circles are characteristic of medium to fine-textured soils and low gradient landscapes of the Low Arctic, while sorted circles and stone stripes are common in soils with considerable coarse fragments or where slope gradients are high. These features result in 'spotted tundra', with co-occurring well vegetated and sparsely vegetated areas (Ping et al., 2008a,b). Bare, exposed areas typically experience high evapotranspiration and accumulate soluble salts, have higher soil pH, and lower organic matter and carbon

Fig. 3 Representative landscape and soils of the Low Arctic. (A) Sagavanirktok River Valley, Sagwon Hills, northern Alaska, USA (N.A. Jelinski); (B) Aquiturbel (Cryosol) formed in marine sediments near Utqiagvik, Alaska on the Alaskan Coastal Plain (J. D. Jastrow), (C) Haploturbel (Cryosol) formed in loess over glacial till in the Sagwon Hills, Alaska (N.A. Jelinski), (D) Hemistel (Cryosol) formed in organic materials in the Sagwon Hills, Alaska (N.A. Jelinski).

stocks, whereas protected micro depressions in frost cracks are well vegetated, have thick organic matter at the surface, are more acidic, and have larger carbon stocks.

Frost-cracking in fine- to medium-textured sediments is largely responsible for patterned ground formation and the accumulation of extensive ground ice. Ground ice content in the Low Arctic, with the exception of mountainous areas, is generally higher than that of the Subarctic and Boreal. Due to colder and drier conditions and extensive frost cracking, reticulate cryostructures, with vertical cracks or ice nets, ice veins and wedges, as well as suspended (ataxitic) cryostructures and massive ground ice are common (Ping et al., 2008a,b). Cryoturbation processes are dominated by cracking and warping, hydrocryostatic and cryostatic pressures, diapirism, and differential frost heave.

- **Classification and Carbon stocks.** Gelisols (Cryosols) cover 90% of the ice-free land area in the Low Arctic. Most remaining soils of the Low Arctic are Entisols (Regosols), Inceptisols (Cambisols), or Mollisols (Chernozems). These minor soils typically occur on floodplains, steep, rocky slopes, or in coarse textured soils on colluvium where near-surface permafrost is not present, despite cold annual average temperatures. Extensive cryoturbation as well as burial due to eolian or alluvial activity has led to the development of large carbon stocks in mineral soils of the coastal plains and river deltas of the Low Arctic. The SOC stocks in Low Arctic mineral soils to 1-m depth typically range from 10 kg C m^{-2} to $>80 \text{ kg C m}^{-2}$ (Ping et al., 2008a,b), and the soils of permafrost-affected peatlands in the Low Arctic can exceed $>100 \text{ kg C m}^{-2}$.

High Arctic soils

The High Arctic cold regions (Arctic bioclimate zones A, B, and C, Walker et al., 2005) are associated with pergelic and hypergelic MASTs, and near-surface permafrost is continuous across the landscape (Ping et al., 2008a,b). Naturalists have long had a variety of names for the High Arctic sectors, such as 'high polar,' 'polar desert,' 'cold steppe,' 'arctic wastes,' 'rock desert,' 'polar tundra,' 'barren-ground tundra,' 'fell field' (desert-like), 'desert glacial,' 'nival zone,' and 'dry periglacial zone.' The High Arctic can be broadly differentiated from the Low Arctic in that southern air masses almost never reach the High Arctic, and shrubs, where they do

occur, are prostrate and creeping. In Arctic bioclimate subzone A (often identified as the 'Arctic polar desert'), woody species do not occur at all.

- **Climate.** In High Arctic subzones B and C, average high temperatures in summer are typically between 5° and 10 °C, and in winter –10 to –30 °C. Annual average rainfall ranges from <100 to 150 mm, with an additional 50–200 mm of snow water equivalent. In the High Arctic subzone A, average high temperatures in summer are rarely above 5 °C and in winter average highs are typically between 20 and 30 °C. Annual average rainfall in subzone A is <50 mm, with an additional 50–200 mm of snow water equivalent. Approximately 25–75% of the total annual precipitation falls as rain in subzones B and C, whereas in subzone A less than 30% of total annual precipitation falls as rain during the growing season. Low precipitation in the High Arctic leads to several desert-like features. However, there are major differences between High Arctic environments and true low latitude deserts; importantly permafrost results in sub-irrigation of soils during the growing season and the hyper cold temperatures and short growing season results in low evapotranspiration. Therefore, evapotranspiration and precipitation are more closely balanced in the High Arctic than in true deserts (Bliss, 1977).
- **Vegetation.** The High Arctic regions have a discontinuous, sparse vegetative cover (Fig. 4). Vascular plants do not compete for open space as they do in the Low Arctic zone. Vegetative cover decreases polewards in the High Arctic. In subzones B and C, the vegetation of mesic sites is dominated by hemiprostrate and creeping dwarf shrubs (*Salix* sp. L. and *Dryas* sp. L., < 40 cm in height), but cover is interrupted frequently by bare soils associated with patterned ground. There are some wetland plant communities in subzones B and C dominated by the tussock sedges *Carex*, *Kobresia*, and *Eriophorum* sp. In subzone A, there are no woody species and most plants have a compact, 'cushion-type' growth form (Walker et al., 2005). The plant cover consists mainly of lichens, mosses, liverworts, and a scattering of Arctic–Alpine herbaceous plants; sedges are rare, and wetlands, where they do exist, typically lack organic layers. Ecological and pedological differences between well drained and poorly drained sites

Fig. 4 Representative landscape and soils of the High Arctic. (A) Banks Island, Canada (Canadian Arctic Archipelago) landscape and land cover (C.-L. Ping); (B) Poorly drained Glacial Aquiturbel (Cryosol) under hummocks, Isachsen, Ellef Ringnes Island, Canadian Arctic Archipelago (C.-L. Ping), (C) Well-drained Orthel (Cryosol) on a ridgetop under lichen barrens, Isachsen, Ellef Ringnes Island, Canadian Arctic Archipelago (C.-L. Ping), (D) Orthel (Cryosol) in Mould Bay, Prince Patrick Island, Canadian Arctic Archipelago (C.-L. Ping).

are minimal, and there are large areas of bare, exposed soil where vegetation is often confined to cracks and depressions in patterned ground or in areas in between hummocks.

- **Soil formation.** Well-drained soils of the High Arctic have several properties associated with deserts such as saline conditions, desert pavements, and wind-abraded rocks. Secondary carbonates and calcite pendants are common. Desert pavements (formed from deflation of fine particles at the surface in dry and windy conditions) usually occur where coarse fragments are abundant in the substrate. In some well-drained soils, there may be a thin oxidized zone in the upper profile. The pH of well drained High Arctic soils varies from ~4.4 to 7.9. Salt crusts of Thenardite (Na_2SO_4) and other minerals can form on some well-drained to xeric sites (Tedrow, 1977). Horizon differentiation is minor other than that induced by the distribution of iron coatings on soil particles in oxidized zones (Fig. 4). The organic matter content of well-drained High Arctic soils is generally low (often <1% SOC), but does increase where vascular plant cover is more continuous. Unlike the Low Arctic and Subarctic/Boreal, fire disturbance is non-existent.

In lowland soils of the High Arctic, organic matter contents in surface horizons may reach 5%, with greater carbon accumulations in small poorly drained areas with peat at the surface. These soils typically lack carbonates in the upper profile and may have slightly acidic reactions in surface horizons. Hydric soils are also less prevalent (Bliss, 1977) because biological activity is slow (due to cold temperatures) and organic matter contents are low – therefore iron reduction and gleization take much longer to occur. Patterned ground in the High Arctic is largely related to frost-cracking and rock sorting because there is not enough moisture for large amounts of ground ice, except in isolated wetland conditions, where ice wedge polygons can form (Bliss, 1977).

- **Classification and Carbon stocks.** Over 99% of the ice-free High Arctic landscape is underlain by near-surface permafrost and nearly all soils are classified as Gelisols (Cryosols). Controversy remains as to whether carbon stocks have been over- or under-estimated in High Arctic soils, but it is clear that carbon stocks are lower in the High Arctic than in the Low Arctic, Subarctic, and Boreal. Carbon stocks to 1-m depth, regardless of topographic position and hydrologic setting, rarely exceed 25 kg C m⁻² (Ping et al., 2008a,b).

Soils of the southern circumpolar region

The soils and landscapes of the Southern Circumpolar Region (SCR) are far from a mirror image of the NCR. While the NCR comprises an oceanic core (the Arctic Ocean) surrounded by islands and continents, the SCR has a continental core (Antarctica) with outlying islands surrounded by open ocean. These differences make the soils of the SCR unique in several ways. First, there is much less ice-free land at latitudes greater than 45° in the SCR than in the NCR (<50,000 km⁻² and >17 million km⁻², respectively), and in addition, of the 2 to 3% of continental Antarctica that is free of ice and snow, only a small percentage is underlain by unconsolidated materials; the remainder of the ice-free land consists of bedrock and boulder fields. Second, the continentality of the SCR core leads to much colder temperatures than in the NCR (Tedrow, 1991). Third, the soils of the SCR are predominantly maritime influenced, because of the large system of islands and coastal areas. One of the most important effects of this is the major role of colony-forming sea birds that result in unique soil properties. Although such colonies exist in the NCR (Otero et al., 2018), the effects are more intense in the SCR because the ratio of bird populations to ice-free land area in the southern hemisphere is much higher (Otero et al., 2018). The effects that these colonies have on SCR soils are tremendous, and result in unique soil formation processes (collectively known as ornithogenesis), which can lead to increased carbon and phosphorus stocks (Rodríguez et al., 2021), and generally greater acidity and chemical weathering.

The cold soils of the SCR can be broadly divided into four zones: the Subantarctic Tundra (the northern Antarctic peninsula, south Shetland islands, all of the Subantarctic islands south of the Antarctic convergence), and Subantarctic Forest (islands south of the subtropical front and the Antarctic convergence and maritime southern coastal Patagonia (the Chilean Fjords south of 46°S), Tierra del Fuego), the Polar Desert (most of maritime western Antarctica and the central portion of the Antarctic Peninsula between 65 and 68°S), and the Cold Desert (the ice free portions of Antarctica south of ~68°), (Tedrow, 1977; Bockheim and Ugolini, 1990) (Fig. 5).

Soil parent materials. Almost all of ice-free Antarctica and most of the SCR was glaciated during the Pleistocene, except for a few areas which remained ice-free such as the Friis Hills of Antarctica. Most of western Patagonia, western Tierra del Fuego and many of the Subantarctic islands were completely glaciated during the early- to mid-Pleistocene, but glaciation was more limited at the last glacial maximum (Rainsley, 2019). The Subantarctic islands are largely volcanic, but have been modified by ice sheets during previous glacial periods. The South Georgia Islands were completely covered by ice during the last glacial maximum (Clapperton et al., 1989), whereas the Campbell, Falkland and Auckland Islands, for example, may have experienced only limited glacial cover in the late Pleistocene. Soil parent materials are therefore dominated by glacial deposits (till, outwash, glaciolacustrine materials), with eolian sands, colluvium and alluvium occupying most of the rest of the landscape. Unlike the NCR, loess is largely absent from the SCR.

Soils of the Subantarctic Forest and Subantarctic Tundra

The Subantarctic Forest and Subantarctic Tundra belong to a maritime system, consisting solely of coastal regions and islands. The Subantarctic Forest includes much of Tierra del Fuego and the western Patagonian fjords south of 45° S. The Subantarctic Tundra includes islands south of the Antarctic convergence. In latitudes 45 to 60° S of the Subantarctic zone, permafrost is largely non-existent, and average temperatures exhibit little annual fluctuation.

Fig. 5 Pedological zonation, permafrost extent, and soil temperature regimes of the Southern Circumpolar region. (A) Pedological zones are re-interpreted from Tedrow (1977) and Bockheim and Ugolini (1990). The northernmost Subantarctic Forest boundary here includes the maritime portions of western Patagonia and Tierra del Fuego south of 45° latitude. Ice-free areas only are shown and the distribution of ice-free areas is taken from Obu et al. (2019a). (B) Permafrost extent in ice-free areas is derived from (Obu et al., 2019a), assuming permafrost probabilities of 0–9% are equivalent to isolated permafrost, 10–29% are equivalent to sporadic permafrost, 30–89% are equivalent to discontinuous permafrost, and >90% are equivalent to continuous permafrost. (C) Soil temperature regimes for southern South America, New Zealand, and major Subantarctic islands are derived from USDA-NRCS. (2016), while soil temperature regimes for the Antarctic continent are derived from mean annual ground temperature (MAGT) predictions (temperature at the top of the permafrost) from Obu et al. (2019a).

- *Climate.* Average high temperatures are often above freezing for the entire year, and precipitation often exceeds 1000 mm per year. Rain makes up >75% to 90% of total precipitation. In the higher latitudes of the Subantarctic Tundra (South Shetland Islands and northern Antarctic Peninsula, 60 to 65°S), conditions are transitional to the Polar Desert zone. Permafrost becomes sporadic to discontinuous, and annual average temperatures show larger annual variations. Annual precipitation is lower in the southern Subantarctic Tundra, with rain accounting for a smaller proportion of the total.
- *Vegetation.* Subantarctic Forest is limited largely to coastal southern Patagonia, Tierra del Fuego, and the Auckland Islands in New Zealand. The vegetation is dominated by *Nothofagus* sp. in South America and *Metrosideros* sp. in the Aucklands. Most of the Subantarctic region is dominated by tundra, characterized by tussock grasses (*Poa foliosa*) and megaherbs in mesic sites. Natural fire disturbance in the Subantarctic is rare. Vegetated wetlands in the Subantarctic are dominated by rushes, sedges and cryptogams. In the southern latitudes of the Subantarctic Tundra (northern Antarctic peninsula, South Georgia, South Orkney and the Shetland Islands), which are transitional to the Polar Desert, vegetative cover becomes sparse, and consists largely of mosses, lichens, and algae.
- *Soil formation.* The absence of permafrost, relatively mild annual temperatures, and nearly constant precipitation results in excess moisture in the Subantarctic, leading to leaching at well-drained and mesic sites and the accumulation of organic materials in low gradient or poorly drained areas (Fig. 6). Soils are acidic, the accumulation of organic materials is common, and podzolization is common in well-drained soils (Wilson, 2001). Carbonates are largely absent from Subantarctic soils due to intensive leaching processes.
- *Vegetation.* Vegetation cover and biomass production decrease from the northern to southern Subantarctic, while the relative importance of ornithogenesis on soil properties increases. Soils under current or former rookeries tend to be more acidic (pH 3.5–4.5), have higher carbon stocks, and P concentrations up to 10 times greater than adjacent, non-ornithogenic soils. With more acidic conditions and greater carbon and nutrient availability, vegetative growth and microbial activity are elevated in soils under rookeries and biochemical weathering is more rapid than in surrounding areas, leading to changes in mineralogy and chemical properties.

Bouza); (D) Spodosol (Podzol) from the Falkland Islands (R. Burton); (E) Soil with incipient ornithogenic influence due to Skua nesting from King George Island (Courtesy of F. Simas, C. Schaefer, M. Francelino, and R. Michel); (F) Melanized soil on uplifted marine terrace on the Barton Peninsula, King George Island (Courtesy of F. Simas, C. Schaefer, M. Francelino, and R. Michel).

- *Classification and carbon stocks.* Permafrost is largely absent from the northern Subantarctic regions, which are dominated by Histosols (Histosols), Spodosols (Podzols), and Inceptisols (Cambisols). Cold Mollisols (Chernozems), Inceptisols (Cambisols) and some Andisols (Andosols) are also regionally common, for example, in Tierra del Fuego (Rodríguez et al., 2019). Some of the Subantarctic islands may have large areas of Histosols (Histosols) (as thick organic deposits in poorly drained areas and across uplands as blanket peat), and other mineral soils without permafrost. In the southern Subantarctic, permafrost is largely absent at elevations less than 20 m asl, but rapidly becomes sporadic to discontinuous at elevations greater than 50 m asl. Consequently, the southern Subantarctic is a mixture of cold Entisols (Regosols) and Inceptisols (Cambisols) without permafrost at lower elevations and Gelisols (Cryosols) with near-surface permafrost at higher elevations. Data on soil carbon stocks in the Subantarctic are sparse, but estimates suggest that under well vegetated sites in the northern Subantarctic, SOC stocks to 1 m can exceed 30 kg m⁻² (Smith and Karlsson, 2017), and under deep peatlands it may be >100 kg m⁻². In the southern Subantarctic, where vegetation is more sporadic and peat accumulation is rare or highly localized, carbon stocks to 1 m in non-ornithogenic soils are much smaller, often <3 kg C m⁻² (Simas et al., 2007). The SOC stocks in adjacent ornithogenic soils to 1-m depth can be 5–10 kg C m⁻².

Soils of the Antarctic Polar Desert

The Polar Desert zone includes the Antarctic Peninsula (excluding the transitional south Shetland and south Orkney islands) and the ice-free regions of coastal west Antarctica (Enderby land, MacRobertson land, and Wilkes land). Landforms include low hills and moraines with thin to moderately thick glacial drift over bedrock. At elevations less than 300 m, bare, exposed coarse-textured soils and soils shallow to bedrock can be warm enough during the summer to have active layers deeper than 1 m (see Mergelov et al., 2015 Chapter 5 in Bockheim, 2015a,b). At higher elevations, or in most other situations, near-surface permafrost is continuous across the landscape.

- *Climate.* High temperatures in summer (December to February) may reach 5 °C, with mean annual air temperatures between –10 °C and –20 °C. Precipitation is limited almost completely to snow, with total precipitation ranging from 100 to 250 mm year⁻¹ of water equivalent.
- *Vegetation.* Vegetative cover is sporadic, consisting solely of cryptograms (lichens, mosses), and algae. It is most extensive in areas protected from the wind such as drainage pathways and hollows, and under sea-bird colonies. The most extensive vegetation cover occurs as moss cushions, which are closely related to the presence of rookeries. Ornithogenesis is ecologically important in the Polar Desert zone and has a major effect on soil properties at local scales, however, rookeries are less widespread in the Polar Desert zone than in the Subantarctic (Otero et al., 2018).
- *Soil formation.* Most soils of the Polar Desert zone exhibit weakly to well-developed desert pavements (Tedrow, 1977), which are largely absent from most soils in the Subantarctic zones farther north. Continental Antarctica is characterized by high, sustained katabatic winds throughout the year from the action of cold air flowing down from the interior Antarctic plateau. Desert pavements develop from the combination of dry conditions and the action of wind deflation, where wind picks up and removes fine particles, leaving behind a surface covered by coarse fragments. This surface, dominated by coarse fragments protects the soil, preventing further deflation of the materials below. Unconsolidated materials below the desert pavement retain a reasonable amount of moisture during the growing season because of snow melt and thawing of ice in the active layer (see Zazovskaya et al., 2015 Chapter 3 in Bockheim, 2015b).

The lack of vascular flora and sporadic vegetation results in low soil organic matter concentrations in most Polar Desert soils and limited to the upper portions of the soil (see Mergelov et al., 2015 Chapter 5 in Bockheim, 2015a, b). The SOC concentrations are often elevated only at depths less than 5 cm from the soil surface and are commonly <1%, but can range from 1 to 5% (see Zazovskaya et al., 2015 Chapter 3 in Bockheim, 2015a, b). In localized depressions or under more continuous moss cover, SOC contents in the top 5 cm may reach 5–15%, but decline rapidly to <0.5% below 5-cm depth, except under rookeries where SOC contents may remain elevated to depths of 30 cm or more. Shallow peat accumulation (<20 cm thick) can occur in isolated, protected drainage pathways that are better vegetated and accumulate snowmelt during the summer (see Dolgikh et al., 2015 Chapter 4 in Bockheim, 2015a, b).

Soils are sub-irrigated and can be moist in the summer due to snow melt and protection from the desert pavement. There is little to no eluviation, illuviation, and downward movement of soil constituents in the Polar Desert. Thin weakly to strongly oxidized subsoil horizons can occur, but these are typically limited to the upper 20 cm (see Dolgikh et al., 2015 Chapter 4 in Bockheim, 2015a, b). Secondary carbonates occur locally on the underside of coarse fragments, and salts more soluble than carbonates mainly from marine aerosols exhibit patterns consistent with distance from the coast and may occur as salt crusts or efflorescence. Redoximorphic features rarely form, even under frequently saturated conditions because of cold temperatures and low SOC concentrations.

- *Classification and carbon stocks.* Nearly all soils are classified as Gelisols (Cryosols) in the Polar Desert zone. At elevations less than 300 m asl with coarse fragments and little vegetation on exposed areas, the active layer may be deeper than 1 m and soils may be classified as Entisols (Regosols). The SOC stocks are generally low; most soils have <2 kg m⁻² to 1-m depth, while isolated soils with peat at the surface as well as ornithogenic soils may have carbon stocks of 10–20 kg C m⁻² (see Blume and Bölker, Chapter 6 in Bockheim, 2015a, b).

Soils of the Antarctic Cold Desert

Major ice-free areas in the Cold Desert zone include Ellsworth Land, Victoria Land, and the Transantarctic Mountains. Permafrost is continuous, but most surface deposits are not ice cemented because of low moisture conditions which produces dry permafrost (Bockheim, 1997). Active layers are generally very shallow, ranging from <10 cm inland to >90 cm near the coast (Kimble et al., 2021).

- **Climate.** Climatic conditions in the Cold Desert zone are some of the harshest on Earth with total precipitation in water equivalent of 50 to 150 mm year⁻¹, with all precipitation occurring as snow. Summer high temperatures rarely exceed 0 °C, with mean annual air temperatures ranging from –17 to –24 °C (Kimble et al., 2021).
- **Vegetation.** Vegetation cover is sporadic, and where it occurs it is largely algae and lichens. One interesting aspect of Cold Desert zone soils is that there is almost no effective organic component except for local accumulations of guano under penguin rookeries (Tedrow, 1991) (Fig. 7). Orthogenesis is less important in the Cold Desert zone than in the more northerly Polar Desert and Subantarctic zones because rookeries are fewer.
- **Soil formation.** Accumulation of calcite, gypsum, magnesium sulfate, and other soluble minerals is widespread in soils of the Cold Desert. Highly soluble forms of calcium, magnesium, sodium, potassium, chloride, sulfate, and nitrate have also been reported. Nearly all soils of the Cold Desert are alkaline, with pH values 7–10 (Campbell and Claridge, 1987). Closed basins, depressions, and other sites commonly have saline soils and accumulations of salt encrustations. Horizonation is somewhat blurred, with a lack of structural aggregates (Fig. 7). The 'active' layer is less than 1-m thick, but because of the ultra-dry, loose condition, depth to the frost table is often only approximated. There is evidence that there is ionic migration in the soil, even when it is dry and frozen (Campbell and Claridge, 1987). Accumulation of salts is common in the soil in bedrock and boulders.

Physical weathering in the Cold Desert zone is intense. Boulders have shells of exfoliation that can be pried off. Wind polishing of rocks is intense with the abrasion caused by blowing ice particles because it may be as hard as quartz at very low temperatures. Desert varnish is also evident in many places, especially on older land surfaces. The temperature gradient in rocks

Fig. 7 Representative landscape and soils from the Antarctic Cold Desert. (A) Bull Pass, Wright Valley, McMurdo Dry Valleys, Antarctica (C.A. Seybold); (B) Anhyorthel (Cryosol), McMurdo Dry Valleys (M.R. Balks), (C) Anhyorthel (Cryosol), McMurdo Dry Valleys (C.A. Seybold), (D) Typical Anhyorthel, Wright Valley, Antarctica (C.A. Seybold).

on sunny days results in both physical and chemical weathering. Garnets split, feldspars weather, and clay substances accumulate in the fractured areas. Although chemical weathering is less important than physical weathering in this zone, it can still occur over longer timeframes. Increasing oxidation of surface deposits of various ages can occur even in some of the harshest Cold Desert environments (Bockheim, 1997).

- **Classification and carbon stocks.** All soils in the Cold Desert zone are classified as Gelisols (Cryosols). Many soils, due to the dry permafrost conditions, are Anhyorthels (Bockheim, 2015a,b; Kimble et al., 2021). Patterned ground is limited largely to sorted circles and other sorted coarse fragment forms on the soil surface due to the lack of ground ice. Cryoturbation can occur, although it is limited to near-surface horizons. Organic materials do not occur because SOC concentrations are very low, often <1%. Research on SOC stocks in the Cold Desert zone is lacking, however, it is likely that SOC stocks to 1 m do not exceed 1–2 kg m⁻² under most conditions (Bockheim, 2015a,b).

Alpine and Plateau soils

The broad climatic influence of latitude on cold regions declines rapidly beyond the Boreal and Subantarctic regions and requires gains in elevation to achieve cold conditions. As an approximation, every 10 degrees movement south in the northern hemisphere (or north in the southern hemisphere) in latitude requires an additional 1000 m in elevation to maintain similar climate conditions (Bockheim, 2015a,b). Therefore, cold region soils between the 45th parallels are associated with mountainous and alpine environments. These cold areas in otherwise temperate and tropical regions are dominated by the high altitude Qinghai–Tibetan Plateau (QTP, often called the third pole”), a large alpine plateau in the rain shadow of the Himalaya mountains. The remainder of temperate and tropical cold region soils lies predominantly in the US Rockies, Hindu Kush and Himalaya, Andes, Alps and Caucasus mountains, and in a few isolated tropical high mountains in Hawaii, East Africa, and Indonesia.

In these high relief landscapes in otherwise warm latitudes, rapid landscape and vegetation change results in complex and often abrupt pedological and ecological boundaries. Slope and aspect are extremely important in determining solar radiation, soil temperature, and effective soil moisture. With the exception of relatively low gradient landscapes in some areas of the QTP, alpine cold region soils are generally geomorphically active, with high rates of soil erosion and colluvial movement. Parent materials in alpine regions are dominated by gravitationally re-worked glacial sediments and colluvium. Because these soils are in otherwise warm regions of the globe, they are also some of the most rapidly changing areas on Earth.

- **Climate.** The climate of alpine mountainous cold soil regions at latitudes less than 45° N or 45° S is very spatially variable. In many subtropical and tropical cold mountainous regions, diurnal temperature variations exceed those of annual variations in magnitude. Diurnal temperature variation can often exceed 20 to 30 °C, whereas in high latitude cold regions average diurnal temperature fluctuations are more commonly <20 °C. Permafrost in alpine and cold plateau regions is also spatially variable, ranging from non-existent to continuous (Obu et al., 2019b). Although mean annual soil temperatures are often below 0 °C, active layers can be deep due to strong diurnal temperature fluctuations.

Cold plateau soils exist below the snow-line at high elevations on the QTP, the Andes, and mountains of Central Asia. Annual evaporation can exceed 3000 mm in some areas, and the climate can be extremely dry, with aridity indices (the ratio of potential evaporation to precipitation) exceeding 20–40 (Ping et al., 2008a,b). Although mean annual ground temperature (MAGT) in these areas can be less than –3 °C (–2.7 to –1.2 °C at the permafrost table), active layers range from 1 m to more than 3 m thick because of strong diurnal temperature fluctuations, dry conditions, and coarse-textured soils.

- **Vegetation.** Vegetation in alpine and cold plateau regions is generally continuous, except at very high altitudes, where only sparse, discontinuous moss and lichen cover may persist. Forested alpine soils occur in areas with excess moisture (due to regional climate) or in favorable local microclimates (for example on northeast facing slopes in the northern hemisphere), while alpine grasslands typically exist in drier climates. On the QTP, three major vegetation types dominate in order of increasing aridity: alpine meadow, alpine steppe, and alpine desert (Wang et al., 2016) (Fig. 8). The alpine meadows predominate in the eastern portion of the QTP at lower elevations and are characterized by widespread sedge meadows (dominated by *Kobresia* sp.) with minor shrub and forb components. At higher elevations, in the central and western portions of the QTP, alpine steppe dominates the landscape. Vegetation cover in the alpine steppe is less continuous than in the alpine meadows and is generally dominated by cold and dry grasslands (dominated by *Stipa* sp., *Koeleria* sp., and *Festuca* sp.) with minor forb components. Finally, alpine desert occurs at the highest altitudes in the northwestern QTP. These are characterized by sparse vegetation cover, dominated by winterfat (*Ceratoides latens*), thistle (*Ajania fruticulosa*), mustard (*Christolea crassifolia*) and needle grass (*Stipa* sp.).
- **Soil formation.** Cold soils formed under high altitude forests have morphological characteristics typical of excess moisture, such as podzolization, argilluviation and decarbonation, and are moderately acidic, with pH values ranging from 4.8–6.0. In soils under alpine grasslands, podzolization and argilluviation are less common and melanization is more prevalent, resulting in thick, dark colored surface horizons (Munroe, 2012) (Fig. 9).

The alpine meadow zone lies below the high mountain zone and occupies mountain slopes and some lowlands in the alpine zone. The climate is cold, semiarid to subhumid; with MAST of –0.2 to –6.0°C, and MAP of 300–400 mm, with 85–90% falling between June and September. The annual potential evaporation can exceed 2,000 mm and thus the aridity index is often more than 10. The active layer is generally more than 1.5-m thick. In addition to seasonal freeze–thaw, the area also experiences strong diurnal freeze–thaw cycles. The well-drained soils have a dense, black surface horizon, with many fine grass roots overlying a strong brown

Fig. 8 Pedological zonation, permafrost extent, and soil temperature regimes of the Qinghai-Tibet Plateau (QTP). The QTP boundary was derived from Zhang et al. (2014). (A) Pedological zones are based on broad vegetation groupings interpreted from the 1:1 million vegetation map of China (Hou, 2019). (B) Permafrost extent in ice-free areas is derived from Obu et al. (2018), assuming permafrost probabilities of 0–9% are equivalent to isolated permafrost, 10–29% are equivalent to sporadic permafrost, 30–89% are equivalent to discontinuous permafrost, and >90% are equivalent to continuous permafrost overlain on generalized permafrost categories from Brown et al. (2002) to display more localized variation. (C) Soil temperature regimes are derived from USDA-NRCS (2016).

Fig. 9 Representative landscape and soils from low latitude (between 45°N and 45°S) cold alpine regions (excluding the Qinghai–Tibetan Plateau). (A) The headwaters of the Gallatin River, Bozeman, Montana, USA (USDA–Natural Resources Conservation Service. J. Gibson photographer); (B) Pachic Argicryoll (Chernozem), Idaho, USA (Image courtesy of University of Idaho); (C) Xeric Dystricrypt (Cambisol), Idaho, USA (Image courtesy of University of Idaho); (D) Andic Haplocryod (Podzol), Idaho, USA (P. McDaniel).

subsoil, often with an accumulation of carbonates, Fe, manganese oxides, and humus (to a lesser extent) coatings on soil particles, and well-developed reticular and fine, sub-angular blocky structures (Fig. 10). Strong freeze–thaw cycles result in frost-heaved grass mounds, frost cracks, and gelifluction lobes. In lowlands and depressions of the alpine meadow zone, where drainage is limited, gleization features are prominent in the sub-surface horizons. Organic soils form in depressions with restricted drainage.

In the alpine steppe and alpine desert regions, leaching is less extensive due to the arid conditions. In the high mountains and plateau, such as the northwestern Qinghai–Tibet Plateau the aridity index exceeds 10 and can be 40 in some areas. Thus these soils are alkaline and carbonates, gypsum, and soluble salts often accumulate on the soil surface. Organic matter accumulation in alpine steppe and alpine desert soils is less than in the alpine meadow because of colder temperatures and drier conditions, however the grass-dominated ecosystems result in increased OM relative to forested alpine systems (Fig. 10).

Soils formed in alpine and high plateau regions have characteristic morphological features. Strong and frequent diurnal and seasonal freeze–thaw cycles can result in well-developed granular structure in surface horizons due to needle ice formation and reticulate or platy structures in subsurface horizons. Porous cryptogamic crusts are common. These soils can also have cryogenic fabrics such as lenticular and reticulate structures in mountains with high precipitation. On the QTP, however, with its general arid environment, these structures are more abundant in the lower active layers. Rock fragments are not only subject to physical weathering because of freeze–thaw, but also grind against each other during the process, which produces finer particles, especially silt. Thus, many rock fragments in the soil profile are silt-capped. Cryoturbation occurs in these soils and patterned ground such as sorted circles (particularly on exposed ridges and slopes) is common. In addition, these soils can have such strong diurnal temperature fluctuations that freeze–thaw cycles are common even during the summer.

Classification and carbon stocks. Cold soils of alpine and plateau regions are very diverse and are commonly classified as Mollisols (Chernozems), Alfisols (Luvisols), Spodosols (Podzols), Inceptisols (Cambisols), Andisols (Andosols), and Entisols (Regosols), with minor components of Histosols (Histosols). On the QTP, soils under alpine meadow vegetation without near-surface permafrost are commonly Mollisols (Chernozems) Inceptisols (Cambisols), or Entisols (Regosols), while those with near-surface permafrost are Gelisols (Cryosols). Alpine steppe and alpine desert soils verge on aridic soil moisture regimes and may be classified as Aridisols (Calcisols, Gypsisols, or Durisols) or Gelisols (Cryosols). Carbon stocks in alpine and plateau soils are also highly variable, spanning a wide range from less than 4 kg C m⁻² to greater than 30 kg C m⁻².

Conclusion

Understanding cold region soil genesis and distribution is an important part of improving global carbon models and projecting the impact of environmental and ecosystem change throughout the 21st century. Although research on cold region soils has been locally extensive, there are many areas in the NCR and SCR as well as the QTP and low latitude alpine regions where data on soil properties and distribution remain extremely limited. For example, in the US state of Alaska, less than 15% of the ice-free land area (as of 2021) is covered by a modern detailed soil map that can be used for land use and management decisions at a local scale. Additionally, the SCR and Antarctica are often not represented in global maps of soil classes and soil properties. It is critical that ongoing research addresses these gaps in our knowledge because of the importance and urgency of understanding cold region soils in the global context of our changing environment.

Abstract

The boreal ecozone is a continuous vegetation belt dominated by coniferous trees located between latitudes 50° and 70° N in the northern hemisphere. Dominating soil types in this ecozone are Podzols, Retisols, Gleysols, Histosols and Cryosols. Many boreal forest sites are characterized by disturbances such as forest fires. Human impacts result in the effects of unsustainable forestry and many contaminants. All of these disturbances affect the soils. Furthermore, the boreal forest plays an important role in the global carbon cycle. It is a great carbon sink and this aspect could be seriously affected by climate change. The northern high latitudes have experienced considerable warming, which especially affects the permafrost soils.

Key points

- Genesis, properties, distribution and classification of soils of the boreal forest ecozone
- Carbon of boreal forest soils and climate change
- Land use and disturbances in boreal forests and their impact on soils

Introduction

The boreal forest ecozone in the northern hemisphere (boreal means north in the Greek language) covers approximately $15 \times 10^6 \text{ km}^2$. Previously, it was also referred to as the taiga (Russian term). This vegetation belt is dominated by coniferous trees and is located between latitudes 50° and 70° N (Fig. 1). In North America the boreal forest is widespread in Alaska and especially in Canada (Fig. 2). A vast boreal forest zone also exists in Russia and China, whereas the European part is comparatively small (Fig. 3) (McLaren and Turkington, 2013; DeAngelis, 2019).

The boreal biome is characterized by a diversity related to climate (maritime or continental), hydrology (dry, mesic or wet), plant cover and soil type. The climate of the boreal forest is characterized by long-lasting winter snowpack and short summers. Therefore, the growing season is less than 6 months. The amplitude between summer and winter temperatures is usually extreme in continental parts and small in maritime regions of the boreal ecozone. In those areas where the soil temperature is below 0 °C for more than 2 years permafrost occurs and affects the hydrology of the forest causing stagnant water. In addition, the amount of precipitation is associated with the location in the ecozone. Precipitation is low in continental regions and high in maritime regions. A large proportion of the annual precipitation usually falls as snow (McLaren and Turkington, 2013; DeAngelis, 2019).

Many boreal forest sites are characterized by disturbances such as forest fires, snow breakage, and windthrow. Human impacts are unsustainable forestry and various types of contamination. Moreover, the boreal forest is a great carbon sink and is therefore greatly affected by climate change.

Soils of the boreal forest ecozone

Genesis, properties, distribution and classification

The following soil types (named after IUSS Working Group WRB, 2022) occur in the boreal forest: Podzols, Retisols, Histosols, Cryosols and Gleysols (Jones et al., 2010; Thiffault, 2019). Following the Soil Survey Staff, 2014 the soils are named: Spodosols,

Fig. 2 Typical plant cover in the boreal forest, Yukon Canada.

Fig. 3 Typical plant cover in the boreal forest, Northern Finland.

Alfisols, Histosols and Gelisols. Soils influenced by groundwater like Gleysols are referred to in the US Soil Taxonomy only at the suborder level as under aquic conditions. In addition, a few more soil types occur in the boreal forest that are not dominant (in detail: [Zech et al., 2014](#)).

It is the interaction of the pedogenetic factors of climate, geological substrate, topography and vegetation which explains why Podzols, Retisols, Gleysols, Histosols and Cryosols prevail in the boreal ecozone. The climate is characterized by relatively low temperatures, low evaporation and sufficient precipitation to allow infiltration either to the groundwater or to a barrier in the subsoil such as impermeable clay layers, bedrock or permafrost. Therefore, well-drained soils exhibit the effects of leaching processes while poorly drained soils show the effects of water saturation.

The underlying materials of large areas of the boreal zone in North America and Eurasia are characterized by a mix of pre-Quaternary igneous and metamorphic rocks partly covered by Quaternary sediments from various glaciations. In general, this geological substrate is acidic and poor in nutrients.

Thus, the original coniferous forest is closely associated with the climatic conditions and nature of the parent material. The vegetation produces slowly decomposing organic matter which accumulates and produces acids. Thus, most soils are characterized by low pH values. In general exposed parent material like gneiss or granite is covered by cryptogams which cause intense chemical weathering of the rocks. Lichens seem to be more effective than mosses in altering feldspars, for example, to clay minerals ([Jackson, 2015](#)). One reason could be the production of strong organic acids by lichens.

Large areas in the boreal ecozone are relatively level or characterized by gently rolling uplands. Mountainous topography occurs in some areas only. Level areas are characterized by a varying microtopography. Thus, a mosaic of well-drained Podzols and poorly drained Gleysols or Histosols occurs. In the northern or more continental parts of the boreal forest permafrost-affected soils (Cryosols) appear because of the very low winter temperatures. Retisols are common for the southern part of the boreal forest with a thick cover of often loamy Quaternary sediments which have characteristic leaching processes.

Retisols (US: Alfisols)

Retisols, the former *Albeluvisols*, are characterized by the leaching of clay from the topsoil to the subsoil. Retisols have a clay illuviation horizon with an interfingering of bleached coarse textured soil material into the fine textured illuvial horizon. Clay and iron oxides are partly removed from the coarse textured material. In the boreal ecozone they are distributed on level to undulating plains mostly associated with glacial till as the parent material ([IUSS Working Group WRB, 2022](#)).

Podzols (US: Spodosols)

Podzols are widespread in the boreal ecozone. They are usually distributed under coniferous forest and on non-calcareous nutrient poor parent material. Podzols are characterized by a spodic (gray, leaching of iron (Fe), aluminum (Al) and organic matter) horizon (IUSS Working Group WRB, 2022). In addition to the coniferous litter, the role of litter derived from the understory vegetation has recently been shown to be involved in these processes for boreal forest stands (Hensgens et al., 2020). Thus, the typical podzolization processes in boreal forests with leaching of dissolved organic matter and elements are possibly mainly driven by decomposition of the litter provided by the understory vegetation like *Vaccinium myrtillus*. Podzols have reddish and or dark horizons in the subsoil below the leached gray horizon (Fig. 4). Depending on the climatic conditions, Podzols that are highly enriched with organic matter in the subsoil occur in regions with high precipitation, whereas those with strong enrichment of iron oxides in the subsoil have formed in regions of low precipitation (Sanborn et al., 2011). In many northern regions the soil horizons of Podzols are very shallow. Sometimes, vertical leaching along stones can be found (Fig. 5). In those regions where Podzols have been influenced by frequent intense freeze–thaw cycles in past soil horizons often show the effects of cryoturbation (Fig. 6).

Fig. 4 Podzol profile, Finland.

Fig. 5 Podzol mini profile, Finland.

Fig. 6 Podzol profile, cryoturbated, Finland.

Gleysols (US: Soils with aquic conditions)

Gleysols are those affected by changes in groundwater depths resulting in periods of waterlogging and periods of drying, which lead to the formation of redoximorphic features. The upper part of the soil (reddish color) is characterized by oxidizing conditions while reducing conditions prevail in some parts of every sublayer (grayish color) (Zech et al., 2014; IUSS Working Group WRB, 2022). In the boreal ecozone Gleysols can be found around lakes (Fig. 7) or in floodplains. They are sometimes characterized by cryoturbation.

Histosols (US: Histosols)

In the boreal zone, Histosols (Figs. 8 and 9) comprise soils formed from organic material mostly accumulated as groundwater peat (fen) or rainwater peat (bog) (IUSS Working Group WRB, 2022). Most of the world's peatlands with the soil type Histosol occur in the boreal zone (Wieder and Vitt, 2006). Therefore, Histosols play an important role in this biome because they serve as a carbon sink.

Fig. 7 Gleysol at a lake, cryoturbation indicated by patterned ground, Finland.

Fig. 8 Peatland landscape, Finland.

Fig. 9 Histosol profile with cryoturbation features, Finland.

Cryosols (US: Gelisols)

Permafrost-affected soils (Cryosols) occur in the north and in the continental part of the boreal forest (Jones et al., 2010; Zech et al., 2014). The subsurface layers (cryic horizon), and if present, soil water are permanently frozen. Cryogenic processes (frost heave, cryogenic sorting of solid material, thermal cracking, ice segregation, patterned ground, gelifluction) are the dominant soil-forming processes in most Cryosols (Fig. 10) (IUSS Working Group WRB, 2022). Land use such as agriculture or fire events that remove the vegetation cover has a great impact on Cryosols, because the permafrost table drops down quickly in the profile (Fig. 11). Therefore, decomposition will be enhanced because of the increasing oxygen supply.

Fig. 10 Turbic Cryosol profile, Yukon Canada, red marks at the top of the permafrost table.

Fig. 11 Carbon movement in Cryosols under the influence of land use change.

Carbon of boreal forest soils and climate change

The Intergovernmental Panel on Climate Change, [IPCC \(2018\)](#) stresses that “boreal forests are particularly at risk of climate change-induced degradation and loss, with woody shrubs already encroaching into the tundra (high confidence) and this will proceed with further warming. . . .” This invasion of plants to the north or to subalpine zones and the effects on genesis and properties of soils have been shown for many forest-tundra ecotones of the northern hemisphere ([Moscatelli et al., 2017](#); [Holtmeier and Broll, 2018](#)).

The boreal forest plays an important role in the global carbon cycle. It contains about 30% of the world’s forest carbon stocks and acts as an important carbon sink. The northern high latitudes are experiencing considerable warming. Therefore, boreal forests are becoming more vulnerable to drought, fire and insect outbreaks, for example ([DeLuca and Boisvenue, 2012](#); [Hugelius et al., 2013](#);

Buermann et al., 2014). Permafrost-affected soils are very sensitive to climate warming (Tarnocai et al., 2009; Ping et al., 2010; IPCC, 2018; Stuenzi et al., 2021).

Concern is growing that due to the possible transition from a carbon sink to a carbon source old soil organic matter could be re-introduced into the modern carbon cycle. This risk for mobilization of ancient carbon as dissolved organic carbon and its re-introduction into the modern carbon cycle has been investigated in detail in Podzols of the Swedish boreal forest (Hensgens et al., 2021). Dissolved organic carbon derived from plant litter plays an important role in the carbon balance and the biogeochemistry of forests in general. In addition, the forest floor and thus the carbon stocks of boreal forests in Canada are also sometimes modified by invasive earthworms. The enhanced bioturbation increases the decomposition of the litter (Lejoly et al., 2021).

Peatlands (unfrozen and frozen organic soils) of the boreal region are most affected by climate change because these areas contain large amounts of organic carbon (Wieder and Vitt, 2006). Peatlands have acted as a carbon sink in sequestering carbon during the Holocene. They are also an important global source of methane. Human-induced climate change will change the ecohydrological conditions of the peatlands. These changes are considered to be the primary driving force for future changes of the peatland carbon cycle (Wieder and Vitt, 2006). Approximately 56% of the organic carbon mass in all Canadian peatlands will be severely affected by climate change. It will result in serious degradation of perennially frozen peatlands in the Canadian Subarctic and boreal regions. The degradation in these areas will result in wetter conditions than before during summer. Emissions of methane will be enhanced in this way. On the other hand severe drying of peatlands can occur in the southern parts of the boreal region. Drying of peatlands means increasing decomposition with the consequence of high emissions of carbon dioxide (Tarnocai, 2009; Laamrani et al., 2020; Olefeldt et al., 2021).

Land use and disturbances in boreal forests and their impact on soils

Several types of disturbance in boreal forest ecosystems influence forest soils and therefore biogeochemical processes. Natural disturbances are snow breakage, windthrow, fires and diseases as well as outbreaks of leaf-eating insects and or bark beetles, which may cause severe damage to trees. In mountainous regions mass movements on slopes also affect forest soils by erosion (e.g., Holtmeier and Broll, 2018).

Natural wildfires have been the principle disturbance in boreal forests for a long time. Large amounts of carbon are emitted to the atmosphere because of the combustion of organic matter from the forest floor and the topsoil. Climate warming and drying of the soil have led to an increase in the frequency, extent, intensity and severity of wildfires which could result in the burning of soil organic matter to greater depth. Thus, boreal forests may change from a net carbon sink to a net carbon source, which is a potentially serious problem in relation to the global carbon cycle (Turetsky et al., 2011; Walker et al., 2019).

In addition to the influence of human-induced climate change further human effects on boreal forest ecosystems are related to land use and contamination. Large boreal areas are used by forestry (Wieder and Vitt, 2006), which can affect soil chemical properties such as increasing acidity and soil physical properties like soil compaction can be induced. Meanwhile forest management to preserve ecosystem services and for ecological restoration in relation to carbon sequestration have been focused upon (Safford and Vallejo, 2019; Jørgensen et al., 2021; Kellomäki, 2022).

Boreal forest soils have also become increasingly contaminated. Acidic emissions and heavy metals play a role at the regional level, for example, the copper–nickel industry on the Kola Peninsula has a considerable impact on the plant cover and soils in Finland and Russia (Kashulina, 2017). The contamination affects soil chemical processes and also soil organisms, for example, the contamination with mercury in Swedish forest soils (Xu et al., 2019). In the Canadian boreal forests mining also affects the soils at the regional scale such as the mining of zinc (Hamilton et al., 2016). Mobilization of contaminants from acid sulfate soils should also be mentioned (Yli-Halla et al., 2017). Sulfate is released into the pore water after oxidation of the sulfidic materials in the soil, e.g., after drainage of the soils. Then, the simultaneously produced acidity dissolves metals from the soil matrix. Acid sulfate soils occur in mining areas with peat soil and also in the coastal area around the Baltic Sea. Large amounts of zinc have been leached in these acid sulfate soils (Yli-Halla et al., 2017). Furthermore, contamination by hydrocarbons can have toxic effect on soils, especially in oil mining areas. Depending on the intensity of the contamination Gleysols and Podzols in Siberia can be considered as Technosols (Bykova et al., 2021).

Conclusions

Soils in the boreal zone show great pedodiversity belowground despite the dominant plant cover of coniferous trees aboveground. This is mainly due to the spatial variability in topography and thus drainage conditions. Consequently, in this landscape soils can be dry like Podzols or even waterlogged like Histosols within short distances affecting the chemical and biological soil properties. Soils in the boreal zone are also greatly affected by climate change. Therefore, the impact on the carbon cycle is considerable. The northern and southern ecotones of the boreal zone are indicators of global warming. The southern border is increasingly characterized by deciduous forest and also by agricultural activities. Both kinds of land use change soil properties. The northern border of the boreal zone is characterized by invading trees to the north and also by thawing of the permanently or seasonally frozen ground. This strong anthropogenic impact on boreal soils will also increase the area of contaminated soils which have been localized areas until now, but will be enlarged by increasing industrial activities in the north.

Abstract

Humid cool temperate soils are widely distributed and are some of the most intensively managed soils on the planet due to their favorable properties. The genesis of humid cool temperate soils is dominated by biogeochemical processes operating in moderate temperatures with a pronounced cool season and excess moisture throughout the growing season, resulting in downward leaching of soil constituents and groundwater recharge. In combination with transported soil parent materials, progressive chemical weathering, and distinctive intergrading biomes, humid cool temperate soils represent a unique set of highly fertile soils that are of critical importance to human food, animal feed and fiber requirements.

Key points

- Humid cool temperate ecozones experience excess moisture throughout the year under moderate temperatures with a pronounced cool season.
- These soils are widely distributed on all continents except Antarctica.
- Major trends influencing the development of humid cool temperate soils include, excess moisture, groundwater recharge, youthful parent materials, progressive mineral weathering, and distinctive intergrading forest and grassland biomes.
- Humid cool temperate soils play a disproportionate role in food, animal feed and fiber production.

Introduction and definition of humid cool temperate soils

Humid cool temperate (HCT) ecozones are geographic regions characterized by continental climates with excess moisture and significant seasonal differences in temperature. These ecozones correspond broadly with Köppen-Geiger warm temperate (C) and snow (D) climates, with fully humid (f) and winter dry (d) precipitation regimes and hot summer (a) and warm summer (b) temperature categories. The HCT ecozones are dominated by broadleaf and mixed deciduous forest, grading towards evergreen coniferous forest at the colder boreal limits, humid grassland vegetation at the drier limits and tropical savannah vegetation at the warm subtropical limits. The U.S. Soil Taxonomy (Soil Survey Staff, 2014) and the World Reference Base for Soil Resources (IUSS Working Group WRB, 2015) are useful for defining and classifying soils of the HCT ecozones based on their properties. Where possible, we utilize terminology from both of those systems in this chapter.

Soil temperature and soil moisture regimes in U.S. Soil Taxonomy (STR and SMR, respectively) can define climatic regions more appropriately with regard to pedological (soil forming) processes. The HCT soils have frigid, mesic, or thermic STRs, which correspond to annual average soil temperatures (at a depth of 50 cm from the soil surface) of: 0 °C to <8 °C, with warm summer temperatures (frigid), 8 °C to <15 °C (mesic), and 15 °C to <22 °C (thermic) (Soil Survey Staff, 2014). Within these STRs, HCT soils are additionally restricted to udic (humid) or perudic (aquic) SMRs. The definition of HCT soils as those soils with frigid, mesic or thermic STRs and udic or perudic SMRs notably excludes soils of semi-arid regions that are dominated by mixed- and short-grass prairies in the Great Plains of the United States or the steppes of Eurasia.

This definition of HCT boundaries results in a broad set of geographically distributed soils that have a number of unique pedologic characteristics. Specifically, HCT soils are characterized by: (1) moderate temperatures with a pronounced cool season

that regulate the rate of soil biochemical processes, (2) excess moisture throughout the course of the growing season, which results in downward leaching of soil constituents, (3) surface and groundwater recharge, leading to regionally extensive areas of wetlands, particularly in low-gradient landscapes; (3) a predominance of youthful and transported soil parent materials such as glacial till, loess, or alluvium; (4) progressive chemical weathering processes favoring mineral dissolution and alteration, and (5) an assemblage of distinctive, intergrading biomes dominated by deciduous broadleaf forests, which uniquely influence processes at the plant-soil interface, soil morphology, and specific pedogenetic pathways.

Although HCT ecoregions account for less than 15% of global land area, HCT soils have played a major role in the modern understanding of soil formation and soil genesis. Therefore, soil development in HCT ecoregions has, in many ways, come to represent a central, archetypal conceptual model of pedogenesis. This is partially due to the geographical bias inherent in the development of currently accepted models of pedogenesis (Simonson, 1999; Bockheim et al., 2005) (developed and focused in large part on the eastern United States, western Europe, and Eastern Russia). Despite this historical framing, however, HCT pedogenesis is central only in that it represents an environment between the extremes, and results in changes in soil properties that are readily observable due to gradients in MAT and MAP in HCT regions that align along clear latitudinal and longitudinal gradients. In this chapter we review the distribution, classification, and major pedogenetic themes that unify HCT soils and discuss the impacts of human land management and global environmental change on their properties.

Geographic scope and environmental characteristics, and land use

The HCT soils as defined above fall mainly in the mid-latitude (~ 30 – 60 degrees latitude) regions of the globe (Fig. 1), and are the principal resource for many of the world's most productive and intensively managed agricultural (West et al., 2010) and forest lands (Curtis et al., 2018). Large areas of HCT soils are located across North America (Eastern United States), Europe (southern United Kingdom and France to eastern Russia), Eastern Asia (Eastern/southeastern China and Japan), Oceania (southeastern Australia and New Zealand), and South America (southern Brazil and northeastern Argentina, and southern Chile), ranging in elevation from sea level to ~ 2000 m.a.s.l. (USDA-NRCS, 2016). Soils in HCT ecozones experience humid summers, with adequate precipitation throughout the growing season (in Köppen zones Cwa, Cwb, Dwa and Dwb), or evenly distributed precipitation throughout the entire year (in Köppen zones Cfa, Cfb, Dfa, Dfb).

The HCT ecozones are bounded by cooler boreal regions, where winter air and soil temperatures are lower and growing seasons shorter, and by subtropical and tropical regions, where temperatures are warmer and frosts rarely, if ever, occur. They are also bounded by semiarid and Mediterranean climate regions, where soil moisture becomes insufficient to support the growth of most crops without irrigation during the growing season. Smaller areas of HCT soils may occur outside the dominant latitudes within other ecozones. High elevations and maritime influences are particularly important for generating HCT conditions in tropical and subtropical regions by modifying annual temperature ranges, for example, in mountainous regions of Central and South America,

Fig. 1 Distribution of humid cool temperate zone soils (defined as soils with frigid, mesic or thermic soil temperature regimes and udic or perudic soil moisture regimes, shown by crosshatching) are in the humid temperate Köppen-Geiger climate zones. Soil temperature and moisture regime data are from USDA-NRCS (2016) *Soil Climate Regions Map*. Soil and Plant Sciences Division: Washington, DC <https://www.nrcs.usda.gov/wps/portal/nrcs/main/soils/use/worldsoils/>, and Köppen-Geiger climate zone boundaries are from Beck H, Zimmermann N, McVicar T et al. (2018) Present and future Köppen-Geiger climate classification maps at 1-km resolution. *Scientific Data* 5: 180214. doi: 10.1038/sdata.2018.214.

Sub-Saharan Africa, and Southeast Asia. The HCT regions encompass significant spatial and temporal gradients in temperature, precipitation, and atmospheric moisture deficit that are broadly aligned with latitude (temperature) and longitude (precipitation). The relative timing of these factors is an important determinant for vegetative growth in both natural and managed ecosystems, and has a profound effect on evapotranspiration, infiltration, soil moisture status, and plant available moisture.

The growing season length and temperature in HCT ecoregions is sufficient for the production of major cereal and legume crops such as maize (*Zea mays* L.), barley (*Hordeum vulgare* L.), soybean (*Glycine max* (L.) Merr.), and alfalfa (*Medicago sativa* L.), with accumulated annual growing degree days generally ranging from 2000 to 5000. Mean annual precipitation in HCT ecozones ranges from 700 mm yr⁻¹ to greater than 1500 mm yr⁻¹ and precipitation always exceeds evapotranspiration, resulting in excess moisture in upland soils and groundwater recharge (Fick and Hijmans, 2017). In HCT regions, this precipitation is distributed throughout the growing season and is sufficient for the growth of crops without irrigation, though precipitation may decrease towards the end of the growing season in the drier parts of this region, thus necessitating early-maturing crops like winter wheat (*Triticum aestivum* L.) (You et al., 2014).

In the ‘sweet spot’—the biogeochemical middle ground of the temperate zone

Temperature influences the rates of soil biogeochemical processes, particularly organic matter decomposition, soil mineral weathering, and the rate of oxidation and reduction reactions in soils (Chorover et al., 2007). Typically, a 10 °C increase in temperature will produce a two or threefold increase in the rate of many biochemical reactions (Davidson and Janssens, 2006). The HCT soils, by definition, have adequate moisture throughout the year for biochemical reactions to proceed unhindered, and fall between the temperature extremes of the high and low latitudes, which results in moderate rates of biochemical reactions relative to cold and or arid regions (where soil biochemical reaction rates are generally slower), and subtropical or tropical equatorial regions (where soil biochemical reaction rates are faster).

The HCT soils experience a cool season—even in the southern reaches of their extent there is a pronounced slowing in biochemical reactions during the winter as temperatures cool. These intermediate temperatures lead to differences in the rate of microbial decomposition of soil organic matter compared to higher and lower latitudes, which, in turn, influences organic matter accumulation and soil organic carbon (SOC) stocks in HCT soils. The intermediate character of HCT soil temperature regimes generally means that organic carbon stocks are higher than in soils of similar drainage classes in the subtropics and tropics (Poggio et al., 2021). In contrast, SOC stocks tend to be lower in HCT soils than in soils of similar drainage classes at higher latitudes in colder environments. This same pattern holds true for comparisons of rates of HCT soil mineral weathering with those of lower and higher latitudes in similar drainage classes. Clay mineral assemblages in HCT soils tend to be mixed, intermediate between the relatively unweathered soils of higher latitudes and the highly weathered soils of the tropics and subtropics.

Within the HCT region, these trends are reinforced by the occurrence of large areas of younger parent materials in the cooler parts of the region due to the direct or indirect effects of continental glaciation (Fig. 2). Furthermore, the soil surface may be frozen for a

Fig. 2 Distribution of glacial sediments, loess, and alluvial soil parent materials within humid cool temperate ecozone boundaries. Soil temperature and moisture regime data are from USDA-NRCS (2016) *Soil Climate Regions Map*. Soil and Plant Sciences Division: Washington, DC <https://www.nrcs.usda.gov/wps/portal/nrcs/main/soils/use/worldsoils/>, and parent material data are derived from Beck H, Zimmermann N, McVicar T et al. (2018) Present and future Köppen-Geiger climate classification maps at 1-km resolution. *Scientific Data* 5: 180214. doi: 10.1038/sdata.2018.214.

significant portion of the year in the higher latitudes of the HCT zone, thus sharply reducing the duration of action of many biologically- and hydrologically-driven pedogenic processes. Consequently, soils in warmer parts of the HCT region tend to be more weathered, with lower SOC stocks because of increased rates of organic matter decomposition (Crowther et al., 2019), while soils in cooler parts of the region tend to be less weathered, with higher SOC stocks due to decreased rates of organic matter decomposition.

Excess moisture: Eluviation, illuviation and the leaching of dissolved solutes

In HCT ecozones, precipitation exceeds evapotranspiration losses on an annual basis, which allows the downward movement of excess water through the soil in all but the most poorly drained conditions (where water may be ponded or stagnated). When this downward moving water brings with it soluble soil constituents, the result is a process known as leaching or eluviation. Due to excess moisture conditions, eluviation is one of the most common processes in HCT soils and occurs throughout the year during the period that soils are unfrozen. Most HCT regions experience evenly distributed annual precipitation, however in cooler parts of the HCT with sufficiently cold winters, the accumulation of snow as stored water and its sudden release in the spring can result in bursts of infiltration and leaching in the spring as the soil thaws.

Excess moisture and eluviation in HCT soils results in the dissolution and leaching of ions, dissolved organic matter, fine clays, and soluble ionic compounds (calcium and sodium carbonates (CaCO_3 and Na_2CO_3 , respectively), gypsum (CaSO_4), and more soluble salts). Depending on the average depth and extent to which excess water moves downward over long timescales, these materials then either accumulate in the subsoil (a process known as illuviation) or are removed completely from the soil to the groundwater. Any ionic salts inherited from the soil parent material are rapidly dissolved and leached under HCT conditions. Consequently, HCT soils have been completely leached of salts more soluble than calcium carbonate (CaCO_3 , lime) and, in most parts of the region, are free of calcium carbonate as well. Although of minor importance across the entire HCT region, carbonates may still be found in soils near the semi-arid border of the region, in some isolated, younger, fine-textured soils where restrictive subsoils have not allowed downward leaching over sufficient time periods, and in the rims of wetland basins near the semi-arid border that receive discharge flow.

There are a small number of dominant cations (positively charged ions) that account for the majority of dissolved or adsorbed (attached by electrostatic attraction to soil clays and organic matter) ions in soils. Of these, H^+ (hydrogen) and Al^{3+} (aluminum) are considered acidic cations (Al^{3+} is considered acidic because when released into solution it hydrolyzes, generating additional H^+) and Na^+ (sodium), K^+ (potassium), Ca^{2+} (calcium), Mg^{2+} (magnesium) are considered non-acidic ('base') cations, because they do not hydrolyze when released into solution and thus do not generate additional H^+ (Foth and Ellis, 1997). All else being equal, soils with a greater proportion of acidic cations will have lower pH values ($\text{pH} < 6$), and those with a greater proportion of non-acidic will be closer to neutral ($\text{pH} 6\text{--}7$).

Natural topsoil pH values in the HCT region are generally moderately acidic to neutral, ranging from pH values of 4.5–7 (Poggio et al., 2021). Under the influence of excess moisture, non-acidic cations are lost deeper in the subsoil or completely to the groundwater as acid generating processes from carbonic acid in rainwater, organic matter decomposition, and plant root ion exchange contribute H^+ to the soil. Over time, these H^+ ions undergo exchange with adsorbed non-acidic cations which are lost downwards through leaching, and the topsoil is acidified. Depending on the extent and intensity of leaching, this acidification process can reach great depths, penetrating deep into the subsoil given enough effective moisture and time. This means that the topsoils in HCT regions are, as a rule, more acidic than their underlying subsoils. Because carbonates are the major contributor of OH^- to soil solutions and are responsible for raising soil pH above 7, true alkaline soil conditions ($\text{pH} > 7$) in HCT soils are rare except in special situations described above.

The downward movement of fine clays due to leaching and eluviation and their deposition in the subsoil as laminar coatings on the surfaces of soil aggregates (a morphological phenomena known as 'clay films' or 'argillans' and a process known as 'argilluviation'), is one of the major hallmarks of HCT soils (Bockheim and Hartemink, 2013). Nearly all HCT soils (except those in geologically young and undeveloped deposits of alluvium or colluvium) have clay enriched subsoils that have formed due to argilluviation. This often results in a 'peak' in clay content in the subsoil before the clay content decreases again as the unaltered parent material is approached. This phenomenon is widespread in HCT soils, and these soils have assumed such a central place in the conceptual framework of soil genesis that it is often assumed that all soils become 'clayier' with depth.

A final process associated with excess moisture and eluviation occurs under conditions of intense and rapid infiltration in soils with acidic organic horizons at the surface. Under these conditions, dissolved organic acids can chelate iron oxides that coat soil minerals and transport them to the subsoil where they can accumulate. This process, known as podzolization, results in distinct morphological properties, forming a white or grey leached layer (an 'E' or 'eluviated' horizon) just below the soil surface where iron oxide nanoparticles have been stripped from mineral grains. Below this eluviated zone is often a dark or bright colored zone of illuviation, where dissolved organic matter and chelated iron oxides have been deposited in the subsoil.

Groundwater recharge and wetlands in the humid cool temperate zone

Mineral wetlands, bogs, and fens are common components of many HCT ecozones due to excess moisture, which leads to groundwater recharge and saturation in low-lying areas. Mineral wetlands are particularly common in recently glaciated regions

due to the lack of well-developed dendritic surficial drainage networks and the presence of numerous closed depressions. These wetlands typically form in depressions where runoff from higher elevations collects, particularly if the depressions have restricted drainage or if they intersect the groundwater table. Furthermore, they usually undergo periodic saturation of the soil during the growing season. In non-glaciated parts of the HCT, or in areas of higher relief, mineral wetlands tend to be present only along the margins of surface waters (lakes, streams).

Where saturation is more permanent and the rate of organic matter decomposition is depressed, organic materials accumulate and, if thick enough, can form peat. Although peatlands are not as prevalent across the HCT region as they are in boreal regions or in the vast lowlands of the equatorial tropics, they are of regional importance in many areas. They are also prevalent on low-gradient coastal plains where the groundwater table is near to the soil surface. Ombrotrophic bogs form in areas where groundwater inputs to the organic layers are minimal and nearly all nutrients are supplied by precipitation and inputs from surface runoff. Over time the surface elevation of the center of the bog will increase due to the formation of peat at the surface, producing a raised dome that is not affected by runoff or groundwater inputs. Bogs have low floristic diversity (mosses, adapted tree and shrub species, few forbs) due to their poor nutrient status. Fens have significant groundwater inputs and, therefore, higher nutrient inputs and greater floristic diversity (grasses (*Poa* sp.), sedges (*Carex* sp.), ericaceous shrubs, and a wider range of forbs and herbs) than ombrotrophic bogs. Fens may also form on mild to steep slopes where seepage contributes a steady flow of water downslope causing saturation at the soil surface. Organic horizons tend to form in this saturated environment and, if thick enough, are described as 'hanging fens.' Although not as common, blanket peatlands (extensive areas of continuous peat across the land surface) can form on low relief landscapes in the northern portions of the HCT region, such as in the northern United States, Scotland, and other HCT areas of northern Europe (Xu et al., 2018).

In addition to the process of organic material accumulation, oxidation and reduction (redox) reactions are the major biogeochemical process of importance in HCT wetland soils. Broadly, redox reactions are defined as any chemical reactions that involve the transfer of electrons between two chemical species. In soils, the most prominent redox reaction under aerobic (oxygen-rich) conditions is aerobic respiration by microbes, which oxidizes organic molecules to CO_2 (carbon dioxide) gas; in turn, oxygen (O_2) is used as a terminal electron acceptor and is reduced to water vapor (H_2O). This is an exothermic process resulting in net energy output to the microorganism, the same function that aerobic respiration serves in macro-organisms such as humans. However, when oxygen becomes depleted in soil due to saturated conditions (oxygen diffuses 10,000 times slower through water than through air), microorganisms in soil must use alternate electron acceptors as they continue to decompose organic molecules for energy. After oxygen, the next most favorable electron acceptor is nitrate (NO_3^- , which is reduced to N_2 (nitrogen) gas in a process known as denitrification), followed by manganese (Mn), and then ferric iron (Fe^{3+}). Depending on prevailing temperatures and soil chemical parameters, which can vary in both space and time, it takes approximately 2 weeks to 1 month of saturation for microorganisms to exhaust available oxygen, nitrate, and manganese and begin utilizing iron as an alternative electron acceptor (Fiedler and Sommer, 2004).

Iron is particularly important because it is highly abundant in most soils (2–8% by weight) and oxidized, ferrous iron compounds (iron oxyhydroxides) are responsible for the brown, orange, red, and yellow earth colors—caused by iron oxide nanoparticles—that coat the surfaces of otherwise drab mineral grains. When microorganisms use iron as a terminal electron acceptor in aerobic respiration, ferric iron (Fe^{3+}) is reduced to ferrous iron (Fe^{2+}). Except in unique conditions of high ferrous iron concentrations, ferrous iron does not form stable solid compounds as does ferric iron, so once reduced, the iron simply acts as a dissolved ion and does not affect soil color. The iron oxide nanoparticle 'paints,' which give soils the distinctive earth tone colors, are dissolved, leaving the underlying mineral grains uncoated. Because the most dominant soil minerals are grey in color, this process leaves the soil with a grey or dull appearance. If oxygen is reintroduced into the soil following a period of saturation, any remaining ferrous iron will rapidly and abiotically re-oxidize to ferric iron, re-forming iron oxide nanoparticles, but the reoxidation is never homogeneous. It leaves a splotchy, mottled pattern of brightly colored iron oxide concentrations and dull colored depletions. Collectively, these are known as redoximorphic features (mottling related to the biochemical reduction of iron under conditions of saturation, and the abiotic reoxidation of iron under fluctuating saturated/unsaturated conditions), and they serve as major morphological indicators of soil wetness timing, duration and the seasonal fluctuation of the saturated zone.

A predominance of youthful, transported parent materials

Soil 'age' refers to the time since exposure of a geomorphic surface or soil parent material and, as such, is a measure of the length of time a soil or landscape has been affected by agents that drive pedogenic development in HCT environments. Some landscapes in HCT ecoregions are composed almost entirely of (geologically) young parent materials formed from processes such as continental glaciation, loess deposition, and glacio-fluvial transport (Ehlers et al., 2011; Börker et al., 2018). Other areas are affected by other rejuvenating processes such as alluvial or colluvial deposition. Overall, more than a third of temperate soils are derived directly from recent glacial deposits, loess or alluvium (Fig. 2). If these criteria were expanded to include materials deposited in early and mid-Pleistocene glaciations, thin loess caps that do not comprise the entire parent formation and minor alluvial deposits, this proportion would likely reach beyond 50%, explaining the wide prevalence of high natural soil fertility in the temperate region.

The HCT soils are derived from a broad array of parent materials, ranging from glacially-derived sediments and wind-blown loess, to residuum, alluvium, and colluvium. Despite this wide diversity in parent materials, some generalities can be observed. In the colder parts of temperate regions, particularly in the northern hemisphere, a significant proportion of soil parent materials

were derived either directly or indirectly from processes associated with late Quaternary glaciations (Börker et al., 2018). Many of these soil landscapes formed on glacial drift, glaciofluvial, or glaciolacustrine sediments. Extra-glacial areas near glacial margins were strongly affected by periglacial processes and may also have experienced extensive wind erosion or fluvial re-working. Still other HCT landscapes, often far removed from the glacial margins, were blanketed by varying thicknesses of loess deposits or eolian materials derived mainly from riverine sediment sources associated with the retreat of continental ice sheets (Li et al., 2020). These materials are geologically young and relatively unweathered, with a higher proportion of non-acidic cations and a mineral assemblage containing significant amounts of primary minerals.

In warmer parts of the region, in landscapes not affected by recent glaciation or loess deposition, soils have formed mainly on alluvium (parent materials transported by streams and rivers), colluvium (the material that has accumulated at the base of hillslopes through creep, slope wash, and erosion), or residuum (soil parent material developed from underlying bedrock without undergoing off-site transport) (Börker et al., 2018). Alluvial deposition may result in the abrupt stratification of materials with differing chemical and physical properties and the burial of topsoil horizons, resulting in irregular decreases of organic carbon in some alluvial soils. In contrast, soils formed in colluvium are typically well mixed, poorly developed, and may have a high percentage of coarse fragments. The physical and chemical properties of residual soils (formed from the physical and chemical weathering of the underlying bedrock, also known as residuum) are initially closely linked to those of the underlying bedrock and vary with local to regional lithology. For example, soils derived from fine-grained sedimentary rocks can inherit clay minerals and trace metals (Dere et al., 2013), and calcareous rocks may initially result in soils with higher pH and calcium concentrations. As soils develop in HCT regions over time, however, their chemical and physical properties deviate increasingly from their parent bedrock. In particular, coarse-grained granites and metamorphic rocks (e.g., schists) will give rise to secondary clay minerals and oxides of Al and Fe.

Progressive mineral weathering, alteration, and transformation

Initially, soil mineralogical properties in HCT soils strongly reflect the parent materials from which they form. Mineral assemblage fractions in relatively young soils contain a high proportion of primary minerals such as framework silicates (feldspars, quartz), chain silicates (pyroxene and amphibole), and primary phyllosilicates (micas such as biotite and muscovite). Soils can also inherit secondary phyllosilicates (such as illite or smectite) or other mineral constituents such as soluble salts (e.g., CaSO_4 , calcium sulfate), carbonates (e.g., CaCO_3), phosphates (e.g., CaPO_4) or sulfides (e.g., FeS). In the soil environment, these primary minerals are exposed to more free water, higher oxygen concentrations, and lower temperatures and pressures than the conditions under which they were formed in the earth's upper mantle. This results in thermodynamic instability, and mineral weathering begins. The two major pathways of progressive mineral weathering in soils are transformation (the re-arrangement of bonds in mineral structures without complete dissolution) and neoformation (the in-situ formation of nano-crystalline minerals from the previously dissolved weathering products in the soil water) (Wilson, 1999).

As soils age in HCT environments, mineral weathering through transformation is progressive and occurs by hydration of oxygen bonds, acid-driven dissolution, and oxidation of redox sensitive elements (e.g., Fe^{2+} to Fe^{3+}). Although these are often conceptualized as geochemical processes, they are actually more appropriately biogeochemical processes—driven in large part by the acidity and organic ligands produced by plant litter decomposition, plant root ions and gas exchange, and the microbially-mediated dissolution of minerals. In HCT environments, any salts or ionic compounds are dissolved relatively quickly and removed from the soil over timescales ranging from centuries to millennia. Over longer timescales (thousands to tens of thousands of years), these mechanisms transform inherited mineral assemblages from less thermodynamically favored primary silicates to moderately stable 2:1 phyllosilicates such as illites, smectites and vermiculites. Finally, over timescales of tens of thousands to hundreds of thousands of years, the further alteration of these mineral assemblages results in large accumulations of the most thermodynamically stable secondary minerals, kaolinite and iron and aluminum oxides.

The neoformation of nano-crystalline, clay-sized mineral particles occurs through precipitation of mineral species from the dissolved weathering products of other minerals. There are two major pathways of phyllosilicate neoformation. The first leads to the neoformation of 2:1 expanding phyllosilicates such as smectite, and is favored in semi-arid conditions with large base cation concentrations and seasonal wet-dry cycles. The second leads to the neoformation of the stable 1:1 phyllosilicate kaolinite, and is favored by well drained acidic conditions, where base cation concentrations are lower and silicic acid and aluminum dominate the dissolved ions. In HCT soils, due to conditions favoring leaching and acidification, this second mechanism is the most dominant, meaning that the major pathway of clay mineral neoformation in HCT soils leads to kaolinite (Wilson, 1999).

Therefore, in well-drained HCT soils, initially contrasting parent materials can end up with similar mineral assemblages through both transformation and neoformation processes operating over sufficiently long periods of time. Although all HCT soils lie somewhere on this progressive mineral alteration trajectory, there is wide variability in HCT mineral assemblages due to differences in parent material, age and climatic factors. In the cooler, higher latitude regions of the HCT, where soils are more likely to be formed in more recently transported or glacially derived parent materials of ages ranging from thousands to tens of thousands of years, mineral assemblages are likely to be mixed, with the clay fraction dominated by 2:1 phyllosilicates such as illite, vermiculite, and smectite. In contrast, in lower latitude, warmer areas of the HCT region, where the soils of broad ridgetops and interfluvies have

been weathering in places for tens of thousands to hundreds of thousands of years, kaolinite is often the dominant phyllosilicate mineral in the clay fraction together with iron and aluminum oxides such as hematite and gibbsite (Dere et al., 2013). These broad trends are tempered by significant local variability, depending on parent material composition and drainage class. On balance, HCT soil mineral assemblages represent a middle ground between the intensive weathering processes that occur in the tropics and subtropics, and the much more limited weathering that occurs in cold and arid climates.

The temperate plant-soil interface: Impacts of forest and humid grasslands

Soils and the plant assemblages that grow on them are co-dependent and generate predictable patterns in soil physical and chemical properties, which are a key part of the classical 'organisms' state factor of soil formation. The majority of the native vegetation in HCT ecoregions is dominated by deciduous and mixed deciduous-coniferous forests, followed by humid grasslands and wetland plant communities (Hengl et al., 2018). Other ecosystem types (such as temperate evergreen rainforests) are locally important but are less globally dominant in HCT ecozones. Biomes bounding this region are chaparral or desert scrub ecosystems in more arid regions; annual short- and mid-grass prairies and savannas in Mediterranean regions; coniferous forests in boreal regions; and broadleaf evergreen forests or savannas in the tropics and subtropics.

Deciduous and mixed deciduous-coniferous forests have roots that are coarser, distributed closer to the soil surface, and undergo a much slower rate of root turnover than ecosystems dominated by grasses (Gill and Jackson, 2000). Therefore, the majority of organic inputs in forests are from leaf litterfall and root decomposition, which predominantly occur at or near the soil surface. The incorporation of surface leaf litter and organic matter in forest soils thus requires physical mixing by soil invertebrates such as insects, earthworms, and gastropods. Where leaf materials are not incorporated, the soil typically develops a layer of partially decomposed organic materials at the soil surface, most often termed the forest floor or litter layer, which ranges in composition from nearly intact (fibrous) materials (Oi horizons), to intermediately decomposed hemic (Oe) materials and well decomposed sapric (Oa) materials. These organic (O) horizons play a critical role in seedling recruitment, and serve as a key germination site for seedlings and understory plants. Moreover, the acidity and production of organic ligands by these organic materials can drive the formation of leached layers (E horizons) immediately below them, formed by the eluviation of clays and the chelation and leaching of iron, manganese, and aluminum (hydr)oxides and other coatings from the surface of silt and clay grains in the soil matrix. If earthworms or other invertebrates are present and incorporate the forest floor into the underlying mineral soil, then a relatively thin, light-colored mineral topsoil (ochric epipedon) is observed at the surface. Introduction of non-native and invasive earthworm species into forested landscapes in the northern US has all but eliminated the thick O horizons once common in many of these North American HCT ecozone forests (Hale et al., 2005; Chang et al., 2021).

Soils formed under coniferous forests or mixed deciduous/coniferous forests in HCT regions with coarse, sandy parent materials may have subsoil characteristics resulting from podzolization processes (Lundström et al., 2000). Coniferous leaf litter is more acidic than that of most broadleaf deciduous species, and releases large quantities of dissolved organic acids when decomposed and leached. These organic compounds can chelate Fe, Mn, and Al from metal (hydr)oxide coatings on the soil grains. In relatively coarse-textured soils, the organic acid-metal chelates are transported with the soil solution as long as they remain soluble, producing a distinct, light colored E horizon where surficial metal (hydr)oxides have been removed. The chelated metals are deposited and accumulate lower in the profile due to changes in pH, increases in calcium or clay contents, or other factors, producing distinctive red or black horizons of accumulation of organic matter and Fe, Mn, and Al chelates. The illuvial accumulation of organic matter, iron and aluminum in the subsoil is defined as a spodic diagnostic horizon for the purposes of soil classification (Soil Survey Staff, 2014).

In contrast, soils formed predominantly under deciduous forests in HCT regions with finer parent material display prominent clay accumulation in the subsoil due to the process of argilluviation. Broadleaf deciduous leaf litter is not as acidic as coniferous leaf litter, and therefore true podzolization rarely occurs under broadleaf deciduous vegetation. The downward transport of fine clays is amplified by stemflow phenomena common to deciduous forests, which may concentrate a high proportion of the precipitation falling on a tree directly under its bole, thus producing a localized effect similar to increased precipitation. Therefore, diagnostic subsurface horizons generated by transport of clays or iron oxides are commonly observed. Clay-enriched subsoil horizons dominated by 2:1 phyllosilicates or mixed clay mineral assemblages are defined as argillic horizons in Soil Taxonomy (argic horizons in WRB) and are some of the most common subsoil horizons in the HCT region. A second diagnostic type of clay enriched subsoil formed by argilluviation are the kandic horizons (also argic horizons in WRB), dominated by 1:1 clay minerals such as kaolinite. Kandic horizons tend to be present in soils formed on acidic parent materials, or in more highly-weathered soils in warmer regions of the HCT region (Shaw et al., 2010).

Landscapes of low relief at the drier limits of the HCT regions are often characterized by humid grasslands (locally known as prairies, steppes, Pampas or veld), which are dominated by tallgrass species. Because excess moisture in HCT ecozones favors forest growth, these humid grasslands thrive on fire or grazing disturbance to outcompete the forests, and grasslands can withstand and more readily regenerate from frequent fires than most forests. Fires that start in low relief landscapes are often windswept and can cover very large areas, whereas higher relief landscapes tend to slow or stop the spread of fires.

The formation of thick, dark, organic rich mineral A horizons (mollic epipedons in both US Soil Taxonomy and WRB) is common under humid grassland or humid savanna type vegetation type with a grass-dominated understory (Thorp, 1948). Grasses

have deep fibrous root systems and a rapid rate of root turnover relative to forests (Gill and Jackson, 2000) which, in combination, produce significant inputs of organic matter at depth; no translocation is required to move the organic matter deep into the solum. In addition, the efficient base-cycling of grassland ecosystems leads to a large concentration of non-acidic cations, increasing pH to near-neutral levels in climates where more extensive acidification would be expected under forest vegetation. Subsoil horizon development can be minimal in many recently glaciated grassland soils, which may have no subsoil development at all or have subsoil horizons that have undergone only a moderate degree of development in color or structure relative to the parent material. Other older, more well-developed humid grassland soils may have argillic horizons, but these subsoil horizons are not nearly as common under grasslands as they are under forest vegetation. Several factors interact to inhibit fine clay dispersal and movement in grassland soils, including the presence of organic coatings on mineral grains in the topsoil that tend to bind clays together. Exchangeable Ca contents and pH are also generally higher in grasslands, both of which limit clay dispersion and promote its flocculation.

Classification of humid cool temperate soils

Both U.S. Soil Taxonomy (Soil Survey Staff, 2014) and the World Reference Base for Soil Resources (WRB, UN-FAO, 2015) differentiate HCT soils at the highest levels based on major developmental pathways related to predominant vegetation, climatic and parent material influences on pedogenic processes during soil development. The dominant soil groups in HCT regions are Inceptisols (WRB: Cambisols) and Alfisols (WRB: Luvisols and Alisols), which comprise 23.6% and 20.7% of the total land area, respectively (Table 1). The next most common HCT soil groups are Ultisols (WRB: Acrisols and Lixisols) (16.4%), Mollisols (15.0%) (WRB: Chernozems), Entisols (WRB: Regosols) (13.9%), and Spodosols (WRB: Podzols) (4%). All other soil orders or reference groups make up less than 10% of the region (USDA-NRCS, 2005).

Alfisols (high-base status soils with clay-enriched argillic subsurface horizons), Ultisols (low base status soils with clay-enriched kandic subsurface horizons) and Spodosols (soils with organic matter and iron/aluminum oxide enriched subsurface horizons) are associated mainly with forested landscapes and Mollisols (soils with thick, carbon rich topsoils) mainly with grasslands. Alfisols are more common under broadleaf deciduous forests in cooler, drier climates, and younger landscapes where weathering, leaching, and removal of bases is not as extensive. Ultisols occur under broadleaf deciduous forests in warmer, wetter, and more stable landscapes of the region where soils are more weathered and acidic cations dominate. Spodosols occur throughout the HCT region under coniferous forest vegetation in coarse-textured parent materials.

Entisols (morphologically undeveloped soils) and Inceptisols (minimally developed soils that have some color or structural change in the subsoil) are interspersed throughout the HCT region at erosional or depositional landscape positions, in particular shoulder and back slopes where soil development is limited or where new parent materials have been exposed or deposited by geomorphic processes, such as on floodplains. Entisols and Inceptisols are also common in wetter portions of the landscape where soil development processes are slowed due to anaerobic conditions. Histosols (peatland soils formed in large deposits of organic materials) occur on poorly-drained landscape positions, particularly in glaciated regions, where closed depressions abound.

Table 1 Areal extent and proportion of ice-free land surface for soil orders (Soil Survey Staff, 2014) and approximate WRB Soil Reference Groups (IUSS Working Group WRB, 2015) worldwide and in humid-cool temperate regions.

Soil Order (WRB Reference Group)	Extent		Proportion	
	Earth's Surface (10 ⁶ km ²)	Temperate Regions (10 ⁶ km ²)	Earth's Ice-Free Land Surface (%)	Temperate Ice-Free Land Surface (%)
Inceptisols (Cambisols)	12.8	5.3	9.8	23.6
Alfisols (Luvisols, Albeluvisols)	12.6	4.7	9.7	20.7
Ultisols (Acrisols, Alisols)	11.1	3.5	8.5	16.4
Mollisols (Chernozems, some Phaeozems)	21.1	3.1	6.9	15.0
Entisols (Regosols)	9.0	3.3	16.2	13.9
Spodosols (Podzols)	3.4	0.8	2.6	4.0
Vertisols (Vertisols)	3.2	0.6	2.4	2.7
Andisols (Andosols)	0.9	0.2	0.7	1.0
Oxisols (Ferralsols)	9.8	0.2	7.5	1.0
Aridisols (Gypsisols, Durisols, some Calcisols and Kastanozems)	15.7	0.2	12.0	<0.1
Histosols (Histosols)	1.5	0.1	1.2	<0.1
Gelisols (Cryosols)	11.3	—	8.6	—
Shifting Sands	5.3	0.1	4.1	<0.1
Rock	12.1	10.0	10.0	<0.1

Impacts of land use and management on humid cool temperate soils

Humans have had a profound influence on HCT soils, both directly through agricultural and forestry activities and indirectly through the alteration of global biogeochemical cycles. Although temperate region soils (as defined above) make up only 16% of the world's ice-free terrestrial surface, roughly 1/4 (27%) of the world's croplands lie in HCT regions, and even more of the area is under pasture or other food, animal feed, and fiber production (Yu et al., 2020). Many of the world's most intensively managed forestlands also occur in HCT ecozones (Curtis et al., 2018). This is due, in large part, to the favorable properties of HCT soils and the favorable environments in which they occur.

At regional scales, the long-term human agricultural use of soils in HCT regions associated with the addition of organic materials through heavy manuring has resulted in phosphorus-rich topsoils (plaggen epipedons), which are typically higher in organic matter and absolute elevation (due to upbuilding through the addition of organic materials) than adjacent soils. In North America, Indigenous peoples of the Mississippi River Valley utilized extensive areas of HCT soils for crop production and earth-building activities (Woods, 2004). In the past century, HCT soils have also undergone extensive change at larger scales due to the high density of intensive, mechanized agriculture. Agricultural tillage has caused accelerated erosion on many HCT landscapes through the net downslope movement of soil material disturbed by tillage implements and by leaving soil surfaces poorly protected against raindrop impact. This accelerated erosion can increase the variability of soils across these landscapes; for example, in some parts of the United States Corn Belt the erosion of material from upper slope positions and decomposition of soil organic carbon has resulted in a change from mollic to ochric epipedons, which effectively results in the co-dominance of Alfisols or Inceptisols and Mollisols where Mollisols were once the primary soil order (Jelinski and Yoo, 2016). The fact that these changes have taken place over a time period of less than 200 years in the United States accentuates the tremendous capacity of human activities to change soil properties. At still larger scales, the indirect effects of industrialization, fossil fuel burning (which produces atmospheric deposition of both nitric and sulfuric acid) and the widespread production and application of nitrogenous fertilizers has resulted in the anthropogenically accelerated acidification of many soils in HCT regions.

The artificial drainage of wetlands or seasonally wet soils has been a widespread practice in intensively cropped soils in the HCT zone. The installation of artificial drainage (including both ditching and tile drainage) is most prevalent on a global scale across HCT regions in the northern Hemisphere (Feick et al., 2005), but tile drainage in particular is most prevalent in the flat, glacially modified landscapes dominated by fine textured soils in the corn belt of the central United States (Valayamkunnath et al., 2020) and western Europe (areas such as eastern Denmark (Motarjemi et al., 2020)). Widespread drainage can significantly affect local hydrology and, together with agricultural tillage, can increase aeration of the solum which may enhance the rate of organic matter oxidation and release of soil carbon to the atmosphere in the form of CO₂. The magnitude of this process and its impact on the global carbon budget are, however, currently topics of intense debate.

The HCT forests cover 1.04 billion hectares or 25% of the world's forested areas (Nabuurs et al., 2007) and extensive areas of forest have been replaced by agricultural or urban land uses across North America, Europe, and Asia, particularly between 1800 and the early 1900s. The global logging rate for temperate forests has increased (2–6 million ha yr⁻¹) but is more constant than the dramatic increase in logging in tropical forests from 0.3 but to over 8 million ha yr⁻¹ (Runyan and D'Odorico, 2016) due to intensive, cyclical harvest management in HCT zones. Deforestation and agroforestry directly affect the morphology of forest soils by diminishing surface organic materials on the forest floor and organic matter inputs from roots. Moreover, the conversion of forest impacts the biogeochemical cycling of C, N and other elements tied with tree uptake and storage in HCT forest soils.

Conclusion

The soils of humid cool temperate regions, although highly diverse, are predominantly formed in transported parent materials under forest, grassland, and wetland vegetation. Because they tend to be highly fertile and occur in favorable climates, these soils have been significantly altered by human activities and play a large role in global food security and the global carbon cycle. The sustainable management of these soils depends on our understanding of the processes responsible for their formation and the accurate prediction of contemporary pedogenic trajectories.

Abstract

Most Mollisols–Chernozems are recognized as inherently productive and fertile soils that have formed under prairie–steppe grassland ecosystems. Their characteristics result from their formation under grassland and a cool–arid–temperate climate in the continental interiors of the northern and southern hemispheres. The effective moisture, mineral weathering, clay translocation, and secondary carbonates are the main factors that determine the environment of pedogenesis in prairie–steppe grassland regions. The distinctive characteristics of Mollisols–Chernozems are a black or dark topsoil with a large organic matter content. They have experienced major land-use change from natural grassland to intensive agriculture, which has led to a decrease in soil organic carbon (SOC) content; they are the breadbaskets of the world.

Key points

- Mollisols–Chernozems are the most fertile and productive soils in the world;
- Mollisols–Chernozems develop from prairie–steppe grassland ecosystems or grasslands in the cool–arid–temperate ecozone;
- Commonly have a topsoil with a large organic matter content of and show considerable bioturbation;
- Conversion of Mollisols–Chernozems from grassland to arable land has depleted soil organic carbon.

Introduction

The grassland soils of the cool–arid–temperate ecozone, which have formed in the prairie, steppe ecosystems of the world, have very distinctive properties related to their pedogenesis. The distinctive characteristics of these grassland soils partly reflect the influence of the climate under which grassland vegetation predominates. Most soils that have formed under prairie–steppe grassland ecosystems or grasslands recently converted to agricultural use (Barthold et al., 2013) are classified as Chernozems (Russia, IUSS Working Group WRB, 2022), Kastanozems and Phaeozems (WRB), or Mollisols (Soil Taxonomy, Soil Survey Staff, 2022), and Isohumosols or Black Soils (China). The Canadian system of soil taxonomy does not specifically identify Mollisols, but the Chernozemic, Solonchic and Vertisolic Great Groups are those which most closely fit the diagnostic criteria (Liu et al., 2012; Sorokin et al., 2021). They are widely known as Chernozems or Mollisols, and in this chapter we more or less use these terms interchangeably.

Mollisols–Chernozems are identified by a thick, dark-colored, humus and base rich surface horizon (mollic epipedon) with a high base saturation. They have formed mainly on unconsolidated base rich materials, largely wind-blown, such as loess and glacial till. These soils were, and still are, crucial to the agriculture of their respective countries. Other soil orders that occur in grasslands can form in a range of other ecozones and ecosystems.

This chapter comprises much of what was in the original chapter on grassland soils and for which we acknowledge the original authors. Here, we now focus specifically on the grassland soils of the cool-arid-temperate ecozone; the rangeland soils of more arid regions and the pasture soils of wetter regions are covered in other chapters of this edition of the Encyclopedia. First, we consider the formation of grassland soils and the pedogenetic features of the cool-arid-temperate ecozone where climate plays a major role. These soils have also largely formed at the equatorial and eastern margins of the major ice sheets of the Quaternary period, which means that their parent materials are mainly unconsolidated basic materials such as loess and glacial till. The Mollisols–Chernozems are important agricultural soils worldwide and the pressures on these from intensive agriculture are considered. In the classification section we include terms from both Soil Taxonomy (Soil Survey Staff, 2022) and the World Reference Base for Soil Resources (IUSS Working Group WRB, 2022). It becomes clear that this group of soils varies considerably depending on their location, previous vegetation and local climate. Last, the widespread distribution of this group of soils is illustrated with maps and descriptions of their form in various countries and continents. The soils that formed under prairie (steppe) ecosystems were central to the pioneering work by the Russian scientist V.V. Dokuchaev in the 1870s (Kravchenko et al., 2010; Vysloužilová et al., 2015), and later by Guy D. Smith, the originator of Soil Taxonomy.

Grassland soil formation

The natural areas, where temperate grassland soils occur, are the prairies and steppes of the cool-arid-temperate ecozones of the world. From a global perspective, the distribution of grassland is largely a function of climate, particularly climatic factors that influence soil moisture availability. Effective moisture (annual precipitation minus annual potential evapotranspiration) is a useful index of those factors, although it neglects important seasonal variations in moisture supply. At the broad, continental scale, grasslands occupy regions with intermediate effective moisture, between the humid regions that support forest and arid regions dominated by desert shrub communities and vegetation covers of less than 50%. The soil–water balance in grasslands varies widely, but, in the most extensive grassland regions such as the steppes of Russia and Central Asia or the North American Great Plains, potential evapotranspiration frequently exceeds precipitation both on an annual basis and during the growing season. Large interannual variability in precipitation is common and droughts can cause a marked reduction in plant productivity as well as changes in species composition. Geologic records also indicate longer-term shifts between wetter and drier climates during the Quaternary (the last 1,700,000 years); thus, most grassland soils have formed under a range of climatic conditions and plant communities (Anderson, 2006).

Wind-blown sand and loess are probably the most common geologic materials underlying grasslands, mainly as a consequence of the climatic setting and geographical location. Eolian sand and dust were generated locally within grasslands during past periods of dry climate, for example at the ice margins in the Pleistocene, or are derived from neighboring arid regions. In both cases, the wind-blown sediment can subsequently be stabilized by grassland vegetation and preserved over long time periods (Hanberry, 2021). Grassland ecosystems also thrive on a wide range of other geologic materials, from weathered bedrock to glacial till and alluvium. At the local scale, factors other than regional climate become important in determining boundaries between grassland and other vegetation. Fire, ignited by lightning or by humans, is believed to have maintained grassland or savanna in regions where the climate would otherwise have allowed forest development (Andrade et al., 2022). Recurrent fires generally favor grasses with ground-level or underground growth points over woody plants and shrubs that have most of their biomass aboveground, and in addition the accumulation and stabilization of organic matter in prairie soils (Soong and Cotrufo, 2015).

The distinctive characteristics of grassland soils, with their thick dark-colored, humus and base rich surface horizon, in part reflect the influence of the climatic conditions under which grassland vegetation predominates. The frequent soil-moisture deficits in many grassland regions inhibit the weathering of silicate minerals and the oxidation of organic matter, and favor precipitation of secondary carbonates within the soil profile. Calcium is generally the main exchangeable cation throughout the profile. Ecologic processes also influence grassland soil development. Net primary productivity (biomass production by photosynthesis minus biomass consumed through respiration by the photosynthesizers themselves) is relatively modest in most grasslands, relative to many forest ecosystems. In many grasslands, underground plant biomass is greater than aboveground biomass, in some cases by a factor of 5 or more. As consequence, the fraction of total organic matter input that is added to the soil belowground is larger in grasslands than in forest, where most input occurs in the form of surface litter. Consistent with the relative importance of belowground biomass, burrowing activity by animals appears to be greater in grasslands than in other ecosystems, although the difference is difficult to quantify. There are many observations of remarkably extensive burrowing by earthworms, insects (especially ants and cicadas), and rodents in North American and Eurasian grasslands. Geomorphic processes that interact with pedogenesis may also differ between grasslands and other ecosystems. As noted above, eolian sand and loess deposits are widespread in grassland regions, indicating the potential for past truncation of soil profiles by wind erosion or accretionary processes by dust deposition. The latter can lead to the formation of paleosols, which provide a record of terrestrial sedimentary history (Retallack, 1986; Tabor et al., 2017), and represent a vast archive of information about Earth history (Alexandrovskiy et al., 2022).

Environment of pedogenesis in grasslands of the cool–arid–temperate ecozone

Mineral weathering, clay translocation, and secondary carbonate mineral formation

The typical climatic setting of grassland soils of the cool–arid–temperate ecozone does not favor rapid silicate mineral weathering, although some studies have demonstrated that measurable chemical weathering does occur over periods of thousands to tens of thousands of years. The soil–water balance in this setting does not allow large volumes of water flux through soil; thus, the products of weathering are not effectively removed from the soil profile. In temperate grassland soils, in particular, the cation exchange complex remains dominated by Ca^{2+} (calcium) and Mg^{2+} (magnesium), in contrast to soils with greater throughput of water in which these cations are depleted over time. The base saturation requirement for mollic epipedons is consistent with this observation. The predominance of Ca^{2+} , Mg^{2+} , and other base cations buffers soil pH in the circumneutral range, in which silicate mineral weathering is generally slowest. Divalent cations also inhibit clay particle dispersion and translocation. Ecosystem characteristics and also climate limit weathering and clay translocation in these grassland soils. This is indicated by rapid changes in soil morphology across the grassland–forest transition. With increasing forest density, more prominent eluvial E horizons develop, with a more abrupt downward transition to clay-rich B horizons. Forest soils are reported to have lower pH in upper horizons (under natural vegetation), larger rates of silicate mineral weathering, and increased depletion of total phosphorus than nearby grassland soils. These differences can be explained by contrasting organic matter dynamics, weathering intensity, and clay mobility under the two vegetation types. Organic matter decomposition in grassland tends to produce organic compounds that form strong organoclay complexes and inhibit downward translocation of base cations and clays. Less total organic matter is available under forest to produce resistant organoclay complexes, and these effects combine to facilitate downward translocation of clay. Soils near the transition between present-day forest and prairie (steppe) often show evidence of both ecosystems. This is because this boundary is not static and will shift in relation to changes in climate and vegetation.

Clay translocation in grassland soils is a controversial subject. Argillic horizons (zones of clay enrichment through translocation) are uncommon in grassland soils of Eurasia, except near the grassland–forest boundary. This is consistent with limited clay translocation under conditions of circumneutral pH and abundant exchangeable Ca^{2+} and Mg^{2+} . The German pedologist Arnt Bronger has proposed that these clay-rich horizons represent paleosols buried by loess with much lower clay content. This explanation has been received with skepticism by some North American researchers, but clear evidence for ongoing Holocene loess deposition at some sites suggests that Bronger's hypothesis is plausible (Bronger, 1991; Lucke et al., 2019). Precipitation of secondary calcite (CaCO_3) is almost ubiquitous in fine-textured grassland soils of temperate regions, except in the most humid areas near the grassland–forest boundary. However, secondary carbonates are less common in soils formed in sandy parent materials. In well-drained soils, the processes of secondary carbonate formation are straightforward and are clearly controlled by climate. Soil water contains dissolved Ca^{2+} derived from rainwater, dry dust deposition, or weathering of carbonate or silicate minerals. During major infiltration events, the Ca^{2+} is translocated to deeper soil horizons, but the amount of infiltrating water is insufficient to remove Ca^{2+} completely from the profile. When the soil subsequently dries, the soil water becomes saturated with calcite, which precipitates (the required anion, HCO_3^- , is ubiquitous in soil water). As effective moisture decreases across a grassland region, the depth of frequent wetting decreases and secondary carbonates are concentrated at a shallower depth. When soils are considered across a wide range of climatic conditions, a systematic decrease in depth to the upper limit of secondary carbonates is evident with decreasing effective moisture. At more local scales, however, depth to secondary carbonates is surprisingly variable. This variation may reflect differing soil hydraulic properties, or local topographically controlled differences in the partition of precipitation between runoff and infiltration.

Organic matter accumulation, bioturbation, and structure development

One of the most distinctive aspects of soil formation under grassland in temperate climates, i.e., large organic matter accumulation, was recognized by Dokuchaev (1883) in his early classic of pedology, *Russian Chernozem*. The term 'chern' is Russian for black, therefore 'black earth,' is an apt description of the thick, dark-colored zone of organic matter accumulation, or A horizon, in soils of relatively humid cool temperate grasslands in Russia and the Ukraine (Sorokin et al., 2021). The organic matter derives almost entirely from the decomposition of plants, root exudates and microbial necromass, and an important feature is its long maturation (Vysloužilová et al., 2015). Moving south from the 'chernozem zone' in Russia, effective moisture decreases and A horizons become thinner and lighter-colored, reflecting smaller organic carbon content. Similar trends in carbon content and A horizon color are also observed along east-to-west transects of decreasing effective moisture in the grasslands of central North America (Figs. 1–3) and are likely to be present in other regions. Local anomalies occur within these broad regional trends, in areas where A horizons are being built upwards by ongoing eolian or alluvial deposition, and soil carbon is therefore being sequestered in deeper horizons beyond the depth of most active decomposition (Fig. 3b). A temperature effect that is independent of the soil–water balance is also evident. In North America, soils in the cold grasslands of the northeastern Great Plains store more organic carbon than grassland soils further south that receive similar effective moisture, but have formed under warmer temperatures. Organic carbon content also increases as temperature decreases and precipitation increases, from low- to high-elevation grasslands. The spring and early summer provide the best conditions for humification with the increase in soil moisture from snowmelt (Vysloužilová et al., 2015). The seasonal nature of the climate also results in the formation of stable molecules of large molecular weight that have a long mean residence time in the soil.

Fig. 1 Locations of grassland soil profiles shown in Figs. 2 and 3, within the grasslands of central North America (shaded). 1, Caledonia, Minnesota; 2, Seward, Nebraska; 3, Beaver City, Nebraska; 4, Brule, Nebraska. Boundaries of the grassland region are approximate and encompass numerous outlying patches of forest and savanna, particularly near the eastern margin of grassland.

Fig. 2 Schematic view of soil profiles from humid to semiarid grasslands in central North America (locations shown in Fig. 1), showing typical trends associated with climatic gradients. Climatic normal indicated below each column (MAP, mean annual precipitation, 1961–90; MAT, mean annual temperature, 1961–90). The climate at each site has varied significantly over geologic time but the regional climate gradients are likely to have been maintained throughout the period of soil development. Major soil horizons are indicated. Note that 't' indicates clay accumulation, 'k' secondary carbonates, and 'b' buried horizons covered by younger sediment. All profiles have formed in late Pleistocene loess deposited 25,000–12,000 years ago, except for the soil at Brule, Nebraska. The latter formed in late Pleistocene loess at greater than 75-cm depth and in at least two increments of Holocene loess at less than 75 cm. Thickness of dark-colored upper horizons decreases westward as rainfall decreases from Caledonia to Beaver City. The Brule profile deviates from this trend because renewed loess deposition has buried the upper Ab horizon, and organic matter then accumulated in the newly deposited loess, in effect producing an overthickened A horizon. Thickness of the Bt horizon and depth to secondary carbonates also decrease with decreasing rainfall.

These trends with respect to climate can be interpreted using a simple model, in which total soil organic carbon content is in a steady state, with additions equal to losses. The rate of addition is a function of primary productivity, which increases with both increasing effective moisture and increasing temperature. For example, in the central Great Plains of North America, primary productivity increases by two- to threefold in an east-to-west traverse where annual precipitation increases from 250 to 750 mm. Each year's addition of organic matter is offset by loss through oxidation, largely through microbial activity, of a fraction of the total carbon pool. The fraction oxidized also increases with temperature and effective moisture, but not as fast as primary production. Therefore, a much larger pool of soil carbon is required to maintain a steady state in cool, humid grasslands than in areas that are warmer and/or drier. This model is simplistic, because the climate in most grasslands is too variable to allow a true steady state to be maintained, and various forms of organic matter are oxidized at rates that differ by orders of magnitude. Modeling of soil organic carbon dynamics considers multiple pools of soil carbon that turn over at varying rates (Falloon and Smith, 2010). Nevertheless, the results are still consistent with observed trends of soil carbon content in grassland in relation to climate.

Fig. 3 (a) Profiles of organic carbon content in three of the soils shown in Fig. 2. Total organic carbon storage decreases with decreasing mean annual precipitation. The Caledonia profile also formed in a somewhat colder climate, which further enhances organic carbon accumulation; (b) effect of ongoing loess deposition on carbon storage. The Brule profile, where 75 cm of loess has accumulated in the past 10,000 years contains more organic carbon to a greater depth than the Beaver City profile, where mean annual precipitation is somewhat greater but loess deposition in the same time interval has been less than 40 cm.

Soil texture also strongly influences organic matter content. Regression models to predict soil organic carbon content often include clay content or some other textural index as a key predictor. This effect is related to the formation of complexes containing both humus and mineral particles, which can enhance resistance to organic matter decomposition. Organic carbon associated with coarse clay and fine silt is more stable than the more rapidly turned over portion associated with fine clays. Strongly aromatic humic acids are associated with the coarser clays. Original resistance, complexation with phenolic polymers, and absorption to clay can maintain humic materials in the soil for thousands of years.

Locally, the vertical distribution of organic matter within the soil profile can change rapidly across the transition from grassland to forest. Scattered trees have limited influence on surface soil characteristics, but as the forest becomes denser the addition of organic matter to the soil is increasingly dominated by litter deposited on the soil surface rather than that formed belowground by grass roots. Furthermore, a portion of tree root biomass comprises large, suberized and lignified roots that are longer lived and less readily decomposed than fine grass roots, and therefore contribute less organic matter to the soil on an annual basis. Addition of organic matter, primarily at the surface, and limited bioturbation lead to much thinner A horizons under closed forest than under nearby grasslands. Soils with intermediate A-horizon thickness occur in the grassland–forest transition zone. Enhanced moisture in the litter layer of a shaded forest floor environment results in greater rates of decomposition than in prairie and steppe settings. This increases the production of organic acids which can move through the profile, with the effect of reducing total carbon storage in near-surface horizons under forest (Fig. 4).

Both bioturbation and formation of mineral–organic matter complexes play a role in the development of the fine, exceptionally stable structure of many A horizons in temperate grasslands. Macroscopically, soils under undisturbed natural grassland often have moderate to strong granular structure. Microscopically, these soils display a spongy fabric made up of rounded aggregates with abundant interaggregate pore space. Many of the most stable and well-rounded aggregates are the excrements of soil fauna. Others are produced through extensive burrowing activity and propagation of the fine root network of grasses. An extreme case is represented by soils that are predominantly made up of earthworm casts (Vermustolls and Vermudolls, Soil Taxonomy or Vermic Chernozems, WRB). Aggregates in undisturbed grassland soils are stabilized by mineral–organic matter complexes (particularly microbial polysaccharides that interact with clays of submicron size), fungal hyphae, and other bonding agents, which makes them resistant to physical disruption and slaking or dispersion in water.

Conversion of grasslands to agricultural use results in a reduction of the organic carbon content by 20–50% over 20–40 years. Agronomic tillage practices break up soil aggregates, distributes oxygen and moisture through the plow layer resulting in a loss of organic carbon. This reduces soil water-holding capacity, though effects are small, and structural stability, and may reduce cation exchange capacity.

Dynamics of organic matter after cultivation

The conversion of land-use type from grassland to arable can profoundly change SOC storage through its effects on soil C turnover and distribution in the soil profile. To meet the rapid growth in population and the need for food security, Mollisols have experienced excessive land-use change from natural grassland to intensive agriculture, which has led to a decrease in SOC content. This has led to a deterioration in soil physical properties, greater soil erosion, and an increase in soil degradation. It has been estimated that over the past 150 years of cultivation, SOC content has decreased by almost 50% (Food and Agriculture Organization (FAO) of the United Nations, 2022). Intensive crop management has also caused a loss of plant nutrients, which has caused a

Fig. 4 Soil profiles of contrasting organic carbon content in Minnesota, United States, that were under grassland or forest at the time of public land surveys in the 19th century. The soils formed under identical parent materials and climatic conditions and are in similar topographic settings. Locations shown in Fig. 1.

decline in soil fertility. The major Mollisol regions in Northeast China have experienced a downward trend in carbon source that could further degrade the soil if unsustainable land use and management are disregarded. Long-term traditional continuous cropping and tillage in Northeast China are the major factors that have led to the reduction in SOC content and adverse effects on soil properties (Xu et al., 2020).

Mollisols are inherently productive and fertile soils. They are extensively used for cereal and legume production, and are also important soils in pasture, range and forage systems. The majority of the world's Mollisols are affected by water or wind erosion and also by physical or chemical degradation, including loss of SOC, aggregate breakdown, crusting, plow pan development, and acidification due to their long agricultural history and improper management. Agricultural practices and policies are required to guarantee the sustainable use of Mollisols worldwide. Practices, which have been recommended, include increasing the acreage under minimum or restricted tillage, returning plant residues and adding organic amendments, such as animal manure, to maintain or increase soil organic matter content, and the more systematic use of inorganic amendments, such as agricultural limestone to replenish soil calcium reserves. The Food and Agricultural Organization (FAO) of the United Nations has recently published a report on the 'Global Status of Black Soils' (Food and Agriculture Organization (FAO) of the United Nations, 2022) in which concerns about their intensive use and the aim to establish a global agreement for the sustainability of these soils are raised.

Grassland soil hydrology and its influence on pedogenesis

Closed depressions are common in many midlatitude grassland regions. These include regions that were glaciated during the most recent glacial period, and where there has been insufficient time for a connected drainage system to form. Closed depressions of eolian origin are common in dune fields and loess-mantled landscapes. Depressions can serve either as points of focused groundwater recharge or as discharge areas for groundwater flow systems. Some depressions alternate between these two roles on a seasonal basis. Precipitation and snowmelt in recharge depressions is removed by both percolation and evapotranspiration (unless artificial drainage has been installed). Grassland landscapes containing closed depressions frequently illustrate the concept of a soil *catena*. A catena is a sequence of soils along a slope that have different profile characteristics related to topographic position and different subsurface hydrologic systems. It shows a process-response relation to differences in morphology, erosion, deposition, transport of surface material and leaching. Well-drained soils on broad summits are drier and have moderately deep, dark brown surface colors reflecting more oxidizing conditions. Rates of decomposition are also slow in the relatively cool, wetter soils in depressions or on lower slopes. Soils in some closed depressions display a distinct, light-colored E horizon, which is generally lacking in other grassland soils. Grassland soils in areas of groundwater discharge often accumulate soluble salts, gypsum, and/or secondary carbonate minerals. These minerals form from ions transported to the site by groundwater flow. As water is extracted from the soil by root uptake and surface evaporation, the concentration of ions exceeds the solubility of the minerals and they precipitate, often in order of increasing solubility, along the upward groundwater

flow path. That is, carbonates precipitate first, followed by gypsum and soluble salts; this occurs in Kastanozems (equivalent to Xerolls and Ustolls in Soil Taxonomy). Both the vertical and horizontal distributions of secondary minerals are markedly sensitive to the local topographic and hydrologic setting. In other settings, there is a vertical sequence of secondary mineral formation, from calcite at greater depths through a gypsum enriched zone to soluble salts in shallow horizons. This sequence can lead to large concentrations of sodium (Na) in near-surface soil horizons, either in the form of sodium salts or as Na^+ ions held on cation exchange sites of clay and organic matter (Bischoff et al., 2018). Provided that the soluble salt content is large, soil structure is stable. If the upper part of the soil profile periodically experiences downward fluxes of infiltrated water (e.g., in a depression that is a site of either discharge or recharge depending on the season), then salts will be moved to greater depths. The Na^+ -saturated clay and organic matter particles are then easily dispersed and translocated to form a dense, nearly-impermeable B horizon. Such sodium-affected soils often occur in patches associated with subtle microrelief, such as shallow depressions a few meters to tens of meters in diameter.

Classification of the cool–arid–temperate grassland soils

Soil classification was established by the Russian scientist V.V. Dokuchaev in the 1870s (Kravchenko et al., 2010; Vysloužilová et al., 2015). Dokuchaev devised a genetic classification, which was further refined by Russian, European and American scientists. He identified the five major factors that control soil formation, namely: the nature of the parent material (chemical and mineralogical composition), the climate (especially temperature and precipitation), the influences of organisms—flora, fauna and humans, the topography of the area (relief), and the length of time over which soil formation had occurred (Whalen and Sampedro, 2009). Dokuchaev's approach remains important in most, if not all, of the world's major soil classification systems, such as USDA Soil Taxonomy, which recognizes 12 soil orders (Soil Survey Staff, 2022) of which Mollisols is one, and the World Reference Base for Soil Resources (IUSS Working Group WRB, 2022) which has 32 soil reference groups (RSGs) of which three relate to Mollisols.

The two major world soil classification systems use different terminology for the soils of the cool–arid–temperate ecozone, but they embrace similar soil types. Soil Taxonomy (Soil Survey Staff, 2022) uses the term Mollisol, which is one of the 12 soil orders. Mollisols are variable and the differences are indicated at the suborder level by eight groups—the main ones are Udolls, Cryolls, Xerolls, Aquolls and Ustolls. The WRB has three representative groups that cover this ecozone: Chernozems (equivalent to Mollisol *sensu stricto*), Kastanozems (equivalent to Ustolls and Cryolls of Mollisols) and Phaeozems (equivalent to Udolls and Aquolls).

Dark-colored Chernozems (Fig. 5) occupy the humid end of the climatic range of grassland ecosystems, whereas lighter-colored Chestnut soils occur in the drier grasslands and shrub steppes. The WRB system maintains this subdivision (Chestnut soils become Kastanozems), though with more rigorous definitions. The USDA Soil Taxonomy subdivides most well-drained Mollisols on the basis of climatic setting rather than intrinsic soil properties. Many Mollisols of cold climates, such as those formed under high-altitude grasslands, are included in the Cryoll suborder (Mason and Zanner, 2005). More specifically, Mollisols are most extensive in mid-latitude, mid-continental locations, but are also identified in some colder and drier climates.

Chernozems–Mollisols

The International Soil Reference and Information Centre (ISRIC, Wageningen, The Netherlands) indicates that Chernozems cover an area of ~230 million hectares (see relevant websites below). Both Mollisols and Chernozems belong to the tall grass steppe (for example the Haplic Chernozem, Fig. 6) of the mid-continental regions of the mid-latitudes of Eurasia and North America with forest on the northern margin. These areas have a continental climate with cold winters, hot summers and rain mainly in summer. These soils have a thick dark humus-rich surface horizon (known as a mollic epipedon in Soil Taxonomy and a chernic horizon in the WRB) which is the key feature of Mollisols (Bell and McDaniel, 2000). The topsoil horizon is thick (at least 20 cm, but can be up to 200 cm), very dark-colored, has high base saturation >50%, a moderate to large content of organic matter, has strong biological activity, and a well-developed crumb structure. The texture tends to be sandy loam, and secondary carbonates occur within 2 m of the soil surface. There should be no petrocalcic horizon between 25 cm and 200 cm, no secondary gypsum, and no uncoated sand or silt grains on ped faces. The organic matter content can be up to 10–16%, topsoil pH of 6.5–7.5 and subsoil pH of 7.5–8.5. The large porosity means that the soils are well drained and that there is some translocation to 50–200 cm during wet periods. With the increase in clay content, the structure becomes blocky or weakly prismatic. Water holding capacity is good at ~33% at field capacity and 13% at wilting point. The C:N ratio is typically ~10. https://www.isric.org/sites/default/files/major_soils_of_the_world/set8/ch/chernoze.pdf.

Most Chernozems–Mollisols are naturally fertile and are widely cultivated. They produce a large proportion of the world's grain crops, and are known as the 'breadbasket' regions of the world, such as in the United States, Russia, Ukraine, and Argentina. On their northern borders and at higher altitudes they grade into Kastanozems (WRB) or Ustolls and Cryolls (Soil Survey Staff, ST), and on their southern borders and warmer wetter regions they grade into Phaeozems (WRB) or Udolls or Aquolls (ST).

Fig. 5 Photograph of a Russian Chernozem taken by Professor Peter Schad. The labels refer to the horizons and the scale is given by the 10-cm rule.
<https://www3.lis.tum.de/boku/wrb-working-group/pictures/>

Phaeozems (Udolls and Aquolls)

The Phaeozems of the WRB classification (linked to the Udolls and Aquolls of Soil Taxonomy) cover approximately 190 million hectares worldwide, with ~70 million hectares in the eastern Great Plains of North America, ~50 million hectares in the subtropical pampas of Argentina and Uruguay, and ~18 million hectares in NE China (see relevant websites below). They belong to the warm and wet steppe or prairie and forest prairie. The rates of weathering and leaching are greater than for the Chernozems or Kastanozems that embrace the Mollisol group of Soil Taxonomy, and may contain uncoated sand and silt particles on ped faces. They are less rich in bases than Chernozems and Kastanozems, but they still exceed 50% in the upper meter where there are also no secondary carbonates. These soils still contain sufficient bases and plant nutrients for agriculture, have a large biomass and active faunal activity. They have developed on loess, glacial till and other basic unconsolidated parent materials. These soils have a dark topsoil, a mollic horizon that is thinner than the chernic horizon over a cambic or argic horizon. https://www.isric.org/sites/default/files/major_soils_of_the_world/set8/ph/phaeozem.pdf.

Phaeozems (Figs. 7 and 8) are well drained and fertile, therefore they are widely cultivated for cereals or soybean (*Glycine max* (L.) Merrill), and are also used for cattle ranching.

The characteristics of Phaeozems relate strongly to the greater rainfall (up to 1200 mm per annum) and higher temperatures (up to an average temperature of 18 °C) in the regions where they form. The mollic horizon is less dark and thick (30–50 cm) than that of the Chernozem, is well aerated and is more leached, however it has good water holding capacity especially related to clay enrichment at depth. The organic matter content of the topsoil is ~5%, the C:N ratio is 10–12, and pH is 5–7. The topsoil has a well-developed crumb to blocky structure, and at depth the structure becomes more blocky.

Fig. 6 Photograph of a Haplic Chernozem taken in Russia by Professor Peter Schad. In: *Essentials of Soil Science*, W. Blum, P. Schad, S. Nortcliff, 2018, IUSS, Borntraeger Science Publishers, Stuttgart, Germany. <https://www.iuss.org/soils-4-u/world-of-soils/>

Kastanozems–Ustolls and Borolls of the Mollisols

This component of the Mollisol order (Soil Survey Staff) covers ~465 million hectares (see relevant websites below). These are the soils of the short grass steppe belt, south of the Eurasian tall grass steppe, the western part of the North American Great Plains, and drier parts of the South American pampas region (Argentina, Uruguay and Paraguay). They have a similar profile to Chernozems, but the humus rich topsoil horizon is less deep and less black. They have a more chestnut color (see above) and contain a greater accumulation of carbonates. The mollic horizon is at least 20-cm deep over a cambic or argic horizon, secondary carbonates are within 100 cm, and secondary gypsum might also be present at depths greater than 150 cm (Figs. 9 and 10). The main parent material is loess, but they also form on other unconsolidated materials. They form under a drier climate than Chernozems or Phaeozems with hot summers and cold winters. Kastanozems are fertile soils, but agriculture usually requires irrigation or the use of dry farming methods. There is also a need to avoid salinization by the careful management of water. The main crops are small grains and vegetables, and large areas are also used for grazing. https://www.isric.org/sites/default/files/major_soils_of_the_world/set8/ks/kastanoz.pdf.

The intermittent water regime means that Kastanozems can dry out to a great depth in the dry season, and they might not be completely wetted during wetter periods. They are more prone to soil erosion than the other two types of Chernozem. The physical structure is less favorable than for Chernozems because of the weaker aggregation. The organic matter content of the topsoil is now only 2–4% and rarely exceeds 5%. The base saturation remains above 50% as for the other two types, and the C:N ratio is ~10. The structure is granular to fine blocky, and because it is weaker than for the other two types the aeration and water holding capacity are less. The pH is ~7, but can reach 8.5 at depth.

Fig. 7 Photograph of a Phaeozem taken in Mexico by Professor Peter Schad. The scale is given by the 20-cm rule. <https://www3.lis.tum.de/boku/wrb-working-group/pictures/>

Distribution of Mollisols–Chernozems

Mollisols, Black Soils or Prairie Soils make up about 916 million ha worldwide, which is ~7% of the world's ice-free land surface. Their distribution strongly correlates with native prairie ecosystems, but is not limited to them. They are most prevalent in the mid-latitudes of North America, Eurasia, and South America. In North America, they cover 200 million ha of the United States, more than 40 million ha of Canada and 50 million ha of Mexico. Across Eurasia they cover around 450 million ha; 148 million ha in southern Russia, 34 million ha in Ukraine, and 35 million ha in northeast China. They are common in the South American countries of Argentina and Uruguay, and cover about 89 and 13 million ha, respectively. Mollisols are often recognized as inherently productive and fertile soils. They are extensively and intensively farmed, and increasingly dedicated to cereals production, which needs significant inputs of fertilizers and tillage.

On a world-wide basis, soil scientists generally speak of four major regions of Mollisols (Table 1). One is in central North America radiating across the central plains of the United States, eastern Mexico and southern Canada. The next two appear as a discontinuous belt, which extends across southeastern Europe and central Asia. The western belt begins in the sub-humid steppes of south-central Europe and extends across Russia and into the eastern belt, which is best represented in northeast China. The fourth major region corresponds to the Pampas of South America, covering most of central-eastern Argentina and almost all of Uruguay. Thus, most of the world's 916 million ha of Mollisols occur in three regions of the northern hemisphere and one region south of the equator, the Parana-La Plata basin of South America. The Global Status of Black Soils Report by Food and Agriculture Organization (FAO) of the United Nations (2022, Fig. 2.3) provides a recent global map of the distribution of black soil. Understanding of this distribution, and also the formation, uses and risks of these soils are crucial given that these four major Mollisol regions collectively form the world's natural granary. Intensive cultivation, loss of soil organic carbon (SOC), soil erosion and associated yield suppression are still the problems that threaten future sustainability of agriculture in the different Mollisol regions.

Distribution in North America

Mollisols in North America are most extensive in the central plains, extending from the prairie provinces of Canada across the USA's Great Plains and into eastern Mexico's semi-arid grasslands (Fig. 11). Sizeable areas of Mollisols are present in the more

Fig. 8 Photograph of a Luvic Phaezoem taken in the USA by Professor Peter Schad. The scale is given by the rule in centimeters. In: *Essentials of Soil Science*, W. Blum, P. Schad, S. Nortcliff, 2018, IUSS, Borntraeger Science Publishers, Stuttgart, Germany. <https://www.iuss.org/soils-4-u/world-of-soils/>

mountainous, semi-arid western USA and there are even locally important regions of Mollisols in the humid southeast USA, especially in Florida. The distribution across much of North America suggests their formation requires only two features: (a) fertile parent material, and (b) biota that result in humus formation to a depth of 25 cm or more. The former feature is most commonly associated with Pleistocene-aged sediments, especially till, loess and alluvium. The latter feature usually occurs in prairie ecosystems, which are known for their perennial, deep, fibrous root systems with slow decomposition to form metastable Ca-humic materials.

Distribution in South America

The South American Mollisols extend principally over the Chaco-Pampa region together with patches in Patagonia and Mesopotamia regions in Argentina (8.87 million ha, 32% of the territory), Brazil (Pinheiro Junior et al., 2022) and most of the Uruguayan territory (1.30 million ha, 75% of total land, Fig. 12). The majority of South American Mollisols are in the temperate zone; the mean annual temperature ranges from 14 °C at the southern limit of the Argentine Pampa to 19 °C in northern Uruguay. The Pampa region is a vast and continuous plain, rising slightly and gradually to the north and to the west where level areas alternate with slightly undulating plains and rolling landscapes. The most recent Quaternary deposits at the surface and therefore the parent material of Pampean Mollisols are loess and loessoid sediments to the east and eolian sands to the west of the region. The loess here differs from the typical loess in the northern hemisphere where it comprises 50–70% quartz; the light mineral suite in Pampean loess is generally dominated by an abundance of volcanic glass, with more pyroxenes and amphiboles in the heavy fraction. With regard to the clay fraction there is a clear dominance of illite in the west and an increase in smectite and interstratified illite-smectite to the east, close to the Paraná River.

Fig. 9 Photograph of a Haplic Kastanozem taken in Ecuador by Professor Peter Schad. The scale is given by the 10-cm rule. <https://www3.lis.tum.de/boku/wrb-working-group/pictures/>

All the Pampean (Argentine) Mollisols have a thermic temperature regime although some border on mesic. The moisture regimes are mostly udic and ustic. The Great Group of Argiudolls is undoubtedly the most characteristic of the Argentinean Pampa as well as the most productive, and where agricultural activity is more intense.

Mollisols are the most representative soils in the Pampa grasslands although they are also widely distributed associated with several other dominant soil orders in the northern Chaco and Mesopotamia subtropical regions, and in the cold-temperate parts of Patagonia in the extreme south of Argentina. All Suborders of Mollisols are here; the most extensive being Udolls and Ustolls.

Uruguay has zones of pure Mollisols, pure Vertisols and Mollisol-Vertisol mixtures (Fig. 13). The Vertisols are mentioned because they have many properties similar to Mollisols in Uruguay, such as large organic matter content. Mollisols are distributed all over Uruguay, especially in the western half of the territory. Those in the western region are more fertile, richer in organic matter, and more resistant to water erosion than those in the eastern part of the country. Mollisols in Uruguay have developed from a wide variety of mainly fine or medium textured sediments from basalt. On the acid crystalline rocks of the Precambrian shield, Mollisols have a reddish brown or red argillic horizon, a sandy loam A horizon overlying a clay loam or clay B horizon. A stone line between the two horizons is often evident. They have neither swelling clays nor free carbonates and are more acid with depth. Base saturation does not increase significantly in the lower horizons (B and C) as it does in other Mollisols. Albolls, Aquolls and Udolls Suborders of Mollisols occur in Uruguay.

Distribution in Europe

Russian Chernozems are distributed between 50° to 54° N and extend from the border with Ukraine in the west to the Yenisei River in the east (Fig. 14). Podzolized and leached Chernozems typically cover 45 million ha, while meadow-Chernozems (semi-hydromorphic soils) cover 13.5 million ha. In the steppe region, 52 million ha are typical Chernozems, and 11.5 million ha are meadow-chernozems. In addition, 11 million ha of Kastanozems (Chestnut Soils) and 15 million ha of Humic Cambisols could also be added to the Chernozems of this region. The total area of Chernozems accounts for 52.6% of arable lands in the Russian Federation and approximately 72% of these soils have been cultivated (Sorokin et al., 2021).

Ukrainian Chernozems developed on loess and loess-like sediments cover 25.6 million ha, while those developed on eluvium from limestone, sandstone and slates cover 1.8 million ha (Fig. 15). Humic Cambisols with chestnut properties cover 6.6 million

ha. There are 34 million ha of cultivated Chernozems, which account for 62% of all agricultural lands in Ukraine and approximately 78% of these soils have been cultivated. These soils are in a zone of 737 km north–south (51°18'N to 44°41'N) and 1144-km east–west (24°18'E to 40°12'E). The Ukrainian Chernozems are on a plain, but it is a geologically nonuniform region. The podzolized and leached Chernozems are distributed across the well-drained uplands of the forest steppe and watersheds. The typical Chernozems are widespread on upland plateaus between river valleys and terraces. They also occur everywhere in the northern subzone of the steppe, covering the watershed plateaus. 'Southern' Chernozems are common across the Black Sea lowlands and mid-Crimean peninsula, and on the flat plateaus of the southern steppe. Ukrainian Chernozems are distributed in the forest–steppe and steppe zones of Ukraine, where deciduous forests are the native vegetation in the west (pre-Carpathians) to the forest zone in the north, and ending along the Black and Azov sea coasts. The climate in the forest–steppe zone with podzolized,

Fig. 11 Distribution of Mollisols across North America. From Liu XB, Burras, CL, Kravchenko, YS, Duran, A, Huffman, T, Morras, H, Studdert, G, Zhang, X, Cruse, RM, and Yuan, X (2012) Overview of Mollisols in the world: Distribution, land use and management. *Canadian Journal of Soil Science* 92: 383–402. <https://cdnsiencepub.com/doi/full/10.4141/cjss2010-058>

leached, and typical Chernozems is slightly warmer and milder than in the forest zone. Fig. 16 shows the type of Chernozem described above from nearby Romania (Scheia, near the Moldovan border). The soil has developed on Late Pleistocene loess over calcareous sandstone. The land has the characteristic undulating form with a well-developed Chernozem in the foreground, but a lighter calcareous rich soil in the background with clear evidence of soil erosion on the convex slope. The land in the area is used for cereals and grassland, and there is also deciduous woodland in places.

In Central Europe, Chernozemic soils at various stages of formation are placed in the RSGs of Chernozems, Phaeozems or Kastanozems, with respective qualifiers, e.g., Cambic, Luvic, Salic or Protosalic, Sodic or Protosodic, etc. Classification of these soils in the WRB depends on the presence of chernic or mollic horizons, depth of secondary carbonate accumulation and depth of gleyic or stagnic properties, and may vary from Gleyic or Stagnic Chernozems or Phaeozems to Mollic Gleysols or Stagnosols.

Chernozemic soils developed from glacial tills with naturally poor drainage and waterlogging occur on the moraine plateaus in northern Poland. In SW Poland (the Lower Silesia region), two types of chernozemic soils have developed; the naturally well-drained ('dry') and the waterlogged or artificially drained ('hydromorphic') forms. Both 'dry' and 'hydromorphic' chernozemic soils have developed in SW Poland from thick loess or loess-like materials, and typically have a texture of silt loam throughout the profile, but sometimes they are underlain with glacial till or glaciofluvial sand (Kabala et al., 2019).

Slovakia, like other Central European countries, has two types of chernozemic soils differing in moisture regime, i.e. dry or well-drained and hydromorphic. Both forms occur mainly in the Danube lowlands of southwest Slovakia. Hydromorphic Chernozems mainly occur on flat land in the Danube lowlands, on loess sediments mixed with loamy calcareous alluvial deposits,

Fig. 12 Geographical distribution of Mollisol suborders in Argentina (SAGyP-INTA, 1990) based on 1975 edition of the US Soil Taxonomy. From Liu XB, Burras, CL, Kravchenko, YS, Duran, A, Huffman, T, Morras, H, Studdert, G, Zhang, X, Cruse, RM, and Yuan, X. (2012) Overview of Mollisols in the world: Distribution, land use and management. *Canadian Journal of Soil Science* **92**: 383–402. <https://cdnsiencepub.com/doi/full/10.4141/cjss2010-058>

whereas dry Chernozems occur mainly on the hilly areas of the Danube and usually have a parent material of loess. Dry Chernozems in SW Slovakia have also developed from loess and loess-like materials, and have a loamy or silty-loam texture, and secondary carbonates accumulation starts within the upper 100 cm of the soil profile. The topsoil humus horizon often fulfills the criteria for a chernic horizon according to the WRB classification, therefore these soils typically meet the requirements for Calcic Chernozems.

Chernozems or chernozem-like soils, according to the genesis-based current Hungarian soil classification system, cover 22.4% of Hungary; it is one of the most important soil types in terms of agricultural productivity. They are considered as zonal soils of the Hungarian lowland steppe and forest steppe vegetation. Chernozems are widespread on flat and slightly sloping hilly areas and foothills, where the limiting soil forming factors, such as shallow consolidated parent material, shallow (saline) groundwater and light (sandy) or heavy (shrink–swell clays) textures are absent. The WRB approximate equivalents of the Hungarian chernozemic soils are Phaeozems, Kastanozems and Chernozems, or in some cases they are interpreted as Mollic Vertisols and Mollic Gleysols. Chernozemic soils, in many places, have been cultivated since the Neolithic age (ca. 8000 years BP), and have been affected by profound anthropogenic, climatic and land use influences over the past few thousand years. A good overview about Chernozem formation and distribution in Central Europe is given in Eckmeier et al. (2007).

Distribution in Northeast China

The Mollisols of Asia are primarily located in China, especially in northeast China (Fig. 17). Northeast China includes the provinces of Heilongjiang, Jilin, and Liaoning, and the Hulunbeier League of the Inner Mongolian Autonomous Region. The total area is 1.299 million hectares. The region is 1600 km long on the east–west axis, and 1400 km wide on the north–south axis. Mollisols have developed mostly from steppe, prairie to forest–steppe vegetation in this region. Geomorphologic landscapes in the region are plain terraces and tablelands. Most of region has undulating to rolling topography with gentle slopes. The elevation is around 150–400 m. Mollisols have developed from Quaternary loess-like sediments. The thickness of loess-like materials is 10–15 m. The soils and their parent materials are generally slightly acid to alkaline. The soil texture ranges from loam to light clay, with most sola being predominantly clay loam. The main clay mineral is illite, although some chlorite and montmorillonite occur in certain profiles. The accumulation of soil organic matter is the main process of Mollisol formation. Many other processes are also involved,

such as clayization, (aka, neoformation), eluviation and illuviation, leaching and re-precipitation of carbonate minerals, oxidation and reduction of iron and manganese, salinization, desalinization and albic bleaching. These processes divide the Mollisols into different Suborders and Great groups. Four Mollisol suborders are common to northeast China. Albolls are distributed in Heilongjiang and Jilin provinces only. They account for 31% of the total cropland in the two provinces. Albolls that occur in lowlands are best suited for rice (*Oryza sativa* L.) growing if water is available, whereas those in hilly regions are prone to soil erosion and should be used for afforestation. The Aquolls occur where soil temperature is cooler and have larger organic matter contents

Fig. 17 Distribution of Mollisols in Northeast China. From Liu XB, Burras, CL, Kravchenko, YS, Duran, A, Huffman, T, Morras, H, Studdert, G, Zhang, X, Cruse, RM, and Yuan, X. (2012) Overview of Mollisols in the world: Distribution, land use and management. *Canadian Journal of Soil Science* **92**: 383–402. <https://cdnsiencepub.com/doi/full/10.4141/cjss2010-058>

than their better-drained analogs in the region. The Ustolls are distributed in sub-humid and sub-arid regions, and their land use and management vary. In sub-humid regions with fertile soil and reasonable precipitation during the growing season, Ustolls are used for crop production such as maize (*Zea mays* L.), soybean (*G. max* (L.) Merrill) or wheat (*Triticum aestivum* L.), while most of the Ustolls in semiarid regions are used for livestock production and breeding. Some of the Ustolls continue to have native vegetation consisting of lush and high-quality grasses. These are ideal grazing lands. Udolls cover the center of the Chinese Mollisol area. They are the most important soils for croplands (Liu et al., 2021).

Although the total area of Chinese Mollisols (Black Soils in the Chinese soil classification) cover 1.289 million hectares, accounting for 13.5% of the world total, the continuous area of pure Mollisols in northeast China is 361,920 million ha. Over half of these occur in Heilongjiang Province (i.e., 54.5% of China's total area of Mollisols). The Hulunbeier District of the Inner Mongolian autonomous region and Jilin Province have 22.5% and 19%, respectively, of China's Mollisols, while Liaoning Province accounts for only 4.0% of the total. Although some areas of Black Soils areas were cultivated 200 years ago, most of these soils have been under agricultural production for about 50 years only.

Concluding comments

The cool-temperate grassland soils are an iconic set of soils with Mollisols–Chernozems at their center with variations (Phaeozems–Udolls and Aquolls; Kastanozems–Ustolls and Borolls) related to differences in climate and vegetation. The main areas where these soils develop are the prairies and steppes of the northern hemisphere and the pampa of South America. The climate tends to be continental, with cold winters often with sub-zero temperatures, hot summers and moderate rainfall, and plays an important role in the formation of these soils. The original vegetation was tall or short grassland with forest margins. Mollisols–Chernozems have often formed on parent materials of loess, glacial till and other unconsolidated basic materials. They are characterized by a large and stable organic matter content which makes them inherently productive and fertile. They have a stable well developed granular structure in the topsoil and are well drained. The areas of Mollisols–Chernozems are often

known as the ‘bread baskets’ of the world because of their widespread use for cereals. They have become important for legumes such as soybeans, and for grazing animals in the drier areas. With their intensive use for crops and grazing they have become prone to degradation with the loss of organic matter, aggregate disruption, crusting, development of plow pans, and acidification. These effects have led to increased wind and water erosion which further degrade the soil. With the intensification of management because of the increased demand for food from a growing world population, the pressures on Mollisols–Chernozems is ever increasing. There is an urgent need for continued research to mitigate the effects of management and potential climate change to ensure future sustainability of these soils.

Abstract

The term ‘Mediterranean’ is applied to a specific climate and kind of vegetation that is typical of areas surrounding the Mediterranean Sea but also found in five other world regions, namely California, central Chile, Southwest and South Australia, and the Cape region of South Africa. Because soil-forming factors vary widely among Mediterranean areas, the resulting soils share neither morphology nor genesis. Despite their considerable diversity, the body of properties of soils in the Mediterranean areas makes them significantly different from soils in subtropical and other temperate climatic regions. This justifies separate consideration of the genesis and properties of ‘Mediterranean soils,’ a term that is used here with no intended specific genetic meaning and encompasses all soils in areas with a Mediterranean climate.

Key points

- This chapter compiles the main aspects that explain the genesis and distribution of soils in the five Mediterranean climates of the planet.
- The main characteristic of Mediterranean soils is the discordance between high temperatures and high moisture, allowing the occurrence of a soil leaching season (winter) and soil drying season (summer).
- This particular alternation between seasons leads to coexistence of pedogenic processes such as rubefaction, illuviation and the formation of silica and calcite rich horizons.

Soil-forming factors

Climate

In Köppen’s classification scheme, the Mediterranean climate is designated as a warm, temperate, rainy climate with dry summers (Cs), the wettest winter month receiving at least three times as much rain as the driest summer month. Areas with a Mediterranean climate lie mostly around the Mediterranean sea, and at latitudes of 30–45° on the west coasts of North and South America, and the SW and South coasts of South Africa and Australia. They form transitional zones between the influence of the westerlies of higher latitudes and subtropical high-pressure cells. The winter weather is dictated by the fronts of the westerlies, whereas the dry summer reflects the dominance of the midtropospheric anticyclone. A characteristic common to Mediterranean climates is their location in

transition zones between temperate humid climates and subtropical deserts, experiencing a northward or southward shift in response to the glacial-interglacial cycles during the last three million years (Dallman, 1998). There is a general consensus that the climate has become progressively drier in the summer in most regions with a Mediterranean climate throughout the Quaternary period. These areas are also very susceptible to more frequent and intense droughts as a result of climate change (Safford and Vallejo, 2019).

The Mediterranean climate encompasses an interesting variety of subclimates, as illustrated by the temperature and rainfall data from selected stations listed in Table 1. The mean annual precipitation ranges from 300 to more than 1500 mm, with one or two maxima in the rainy season. Summer drought lasts from less than 2 to approximately 5 months. The mean annual temperature ranges from about 11 °C (e.g., in regions of Anatolia and central Spain) to approximately 19 °C (e.g., in coastal areas of Cyprus), and absolute maxima above 45 °C and minima below –20 °C have been recorded at some stations. The difference between the mean temperatures of the warmest and coldest month is less than 8 °C in some coastal areas affected by cold ocean currents (e.g., San Francisco Bay, California) but exceeds 20 °C in inland areas with little oceanic influence. The difference at stations by the Mediterranean Sea is typically 13–16 °C. From the standpoint of pedoclimate, the contrast in moisture content between winter and summer was used as the basis for defining the *xeric* moisture regime, an important diagnostic criterion in the Soil Taxonomy classification system. Under this regime, the soil zone affecting plant growth is dry for more than 45 days in summer and moist for more than 45 days in winter.

The influence of the Mediterranean climate on soil development can be gleaned by considering two simple parameters, namely: the degree of leaching (*L*) and the actual evapotranspiration (*AET*). The annual value of *L* is calculated as the sum of the excess precipitation (*P*) over potential evapotranspiration (*PET*) for those periods in which $P > PET$ less the soil water-holding capacity (*WHC*). The annual value of *AET* is equivalent to $P - L$. Table 2 shows the water balance for a station with a warm continental Mediterranean climate (Córdoba, Spain) and includes the mean monthly and annual values of *P*, *PET*, *AET*, and *L*. Winter leaching (37 mm) is low, consistent with other Mediterranean stations with mean annual *P* below 600–700 mm, if mean monthly *P* data are used in the calculations. As can be seen from Table 2, the summer drought leaves the soil with little water to meet plant needs and enable mineral weathering and biological activity. The intensity of these processes peaks in autumn and late spring when soil is moist and temperatures are mild. In summary, the relative lack of coincidence between high soil temperatures and high moisture contents precludes strong weathering and continuous biological activity (Torrent, 1995).

The variation in annual rainfall is high in the Mediterranean region. For example, the annual rainfall in Córdoba for the period 1901–2000 ranged from less than 250 mm to more than 1250 mm, i.e., by more than five times. The annual leaching for the same period ranged from 0 to more than 650 mm (at *WHC* 125 mm), with a moderately bimodal distribution (Fig. 1). Because of the

Fig. 1 Frequency distribution of annual leaching in Córdoba, southern Spain, for the period 1901–2000, as calculated from monthly rainfall data for the period, the mean monthly potential evapotranspiration (Table 2), and a soil water-holding capacity of 125 mm.

considerable variation in rainfall, *L* has relatively large values in some years. Mean climatic data thus lead to gross underestimation of the leaching potential of the Mediterranean climate, which is generally significant if the mean annual *P* exceeds 500 mm.

Vegetation

Most Mediterranean areas were once covered with a sclerophyllous forest, which adapts itself readily to both summer drought and light winter frost. The exact nature of this forest in the areas bordering the Mediterranean Sea is difficult to ascertain, but the native vegetation probably included coniferous and broad-leaved evergreen trees. Among the latter, holm oak (*Quercus ilex* L. and *Q. rotundifolia* Lam.), cork oak (*Q. suber*), and Kermes oak (*Q. coccifera* L.) are widespread. Typically sclerophyllous species include wild olive (*Olea europaea* L.), carob (*Ceratonia siliqua* L.), and lentisk (*Pistacia lentiscus* L.). Isolated specimens of stone pine (*Pinus pinea* L.) and large areas of Aleppo pine (*P. halepensis* Mill.) are also commonplace. Degradation of the original forest has often resulted in the establishment of scrub communities that are given local names (*garriga* in Catalonia, *maquis* in France, *macchia* in Italy, etc.) and include cistus (*Cistus* spp.), heathers (*Erica* spp.), gorse (*Ulex* spp.), broom (*Genista* spp.), and thyme (*Thymus* spp.). Some scrub communities probably constitute the original vegetation in areas where either low precipitation or pervious rocks and wind exposure gave rise to habitats that were too dry for the sclerophyllous forest to survive (Dallman, 1998).

In North America, the sclerophyllous forests of western California are rich in species of *Quercus* and *Cupressus* similar to those of the Mediterranean basin (e.g., *Q. agrifolia* Née. resembles *Q. ilex*). In areas with mean annual rainfall below 500 mm, a formation similar to the maquis, namely the *chaparral*, reaches 3 m in height and encompasses bush oaks in addition to species of *Ceanothus* and *Arctostaphylos*. In California, vegetation has been shown to rely on the existing deep water of the subsurface throughout the

vadose zone in the dry season, profiting from water at depths up to several meters reaching the weathering front. This demonstrates the role that deeply weathered rock resources can play during periods of water stress (Dawson et al., 2020). In South America, the Chilean sclerophyllous forest exhibits a completely different floristic composition, but that is remarkably similar in appearance to analogous formations in California; *Quillaja saponaria* Molina, *Lithraea caustica* (Molina) Hook. & Arn., and *Peumus boldus* Molina are especially commonplace. Uncultivated land in the Cape region of South Africa is now occupied by sclerophyllous scrub called *fynbos*, which varies between 1 and 4 m in height and exhibits a bluish-green hue; the only tree is *Leucodendron argenteum* (L.) R. Br., which is accompanied by scrub species pertaining to the Proteaceae, Brassicaceae, and Rosaceae families. Finally, in the Southwest and South Australia Mediterranean areas, the vegetation typically consists of *Eucalyptus* species with coriaceous leaves. The *jarrah* forest with *E. marginata* Donn ex Sm. is typical of areas with a mean annual rainfall of 600–1200 mm; on the other hand, the drier (500–600 mm) *wandoo* zone has a less dense forest of *E. redunca* Schauer (Dallman, 1998).

Lithology and relief

The strong tectonic activity present in Chile, California and the Mediterranean basin generate high mountains, which were partially glaciated during the ice ages. Here sedimentary rocks predominate, but plutonic, volcanic, and metamorphic rocks are well represented in most areas. In the Mediterranean region proper, limestones and dolomites constitute a fairly high proportion of the mountains. Frequent erosion and deposition episodes since the Upper Tertiary have led to the formation of large surfaces covered by fine-grained sediments at the foot of the mountains. These tectonically active regions tend to have soils that are richer in nutrients than those found in tectonically stable Mediterranean areas of Australia and South Africa (Casanova et al., 2021). While the landscape of the South African Cape province comprises ancient low altitude ranges, with valleys between where agriculture is developed, in Australia the extreme flatness of its landscape stands out (Fey, 2010; McKenzie et al., 2004). Here, ancient and stable cratons exposed rocks to millions of years of weathering during periods of different climatic conditions than nowadays, resulting in highly developed soils that have nothing to do with the current climatic conditions.

The abundance of steep slopes in mountainous regions has contributed to make water erosion the principal process in slope development, which was particularly active in drier periods during the Quaternary (e.g. interglacial) with scarce or uneven rainfall and soils without a continuous vegetation cover. In periods of more even rainfall, slope development under a continuous vegetation cover was probably more markedly influenced by soil creep and subsurface water erosion, similar to slopes in humid temperate regions. The strong influence of water erosion is apparent in the slope profiles of many lithologically uniform areas, which, as predicted by geomorphic models, consist of a long, concave element at the foot, a straight middle segment, and a short convex summit.

Structural reliefs with parallel-retreating slopes are commonplace in areas of sedimentary rocks (particularly in the drier regions) and tectonically 'passive' regions. These slopes commonly merge into pediments. Depositional pediment surfaces, which are more common in Mediterranean areas than in humid temperate regions, generally have slopes of less than 1–2% and occasionally extend over tens of square kilometers. Some such surfaces are very old and are covered by strongly weathered soils. Frequently, the reverse of pediment surfaces form with V-shaped creeks or valleys when those surfaces have been dissected to a greater or lesser extent by a central stream and its tributaries.

Studies of soil production on hillslopes in Chile and California indicate that Mediterranean climates, which are usually in a transition zone between arid and humid climates, have higher weathering rates (hence soil production) than their climatic neighbors. This results in a lower residence time (<100 ka) of regolith and therefore a greater contribution of nutrients from bedrock decomposition. In this sense, it has been shown that forests in California and Chile at mid-range rainfall (400–700 mm year⁻¹) are highly dependent on the flow of nutrients from the weathering of the underlying rock (Schaller et al., 2018).

Alluvial plains and their contiguous terraces dominate landscapes over stretches of tens of kilometers in the middle and lower parts of major river valleys, where they support irrigated agriculture. River terrace systems provide excellent soil chronosequences for the study of the major soil-forming processes as the systems formed over long periods during the Quaternary. For instance, the oldest river terraces reach heights of more than 200 m above the present river channel in the river Guadalquivir valley (southern Spain) (Pena and Torrent, 1984).

Time

Because the Mediterranean regions worldwide underwent very limited Quaternary glaciation, their landscapes exhibit geomorphic surfaces of widely different ages. Young Holocene landscapes are found widely in fluvial plains, dune fields and mountainous areas around the Mediterranean basin, California and Chile. In these areas, these younger deposits mesh with older surfaces of Pleistocene age, which are well represented in sequences of fluvial and marine terraces. In some places, those surfaces date back to the Pliocene (e.g. the *raña* surfaces in several parts of Spain), where well developed soils of polygenetic origin are found (Gallardo, 2015). Many features present in Mediterranean soils are attributed to wetter periods during glaciations such as rubefaction in *Terra rossa* soils around the Mediterranean basin and clay illuviation in *Duplex* soils in South Africa, especially on older flat surfaces (Fedoroff and Courty, 2013; Fey, 2010). Both processes mentioned above, would take hundreds of thousands of years to form in Mediterranean climates. Australia is at the extreme end in terms of age of soils in Mediterranean areas, with some landscapes in which the soil cover has been in the same place for millions of years. A considerable part of the Australian area with a Mediterranean climate corresponds to the Yilgarian craton of Precambrian age. This ancient non-tectonically active craton has created a landscape with soil patterns that

respond to millions of years of weathering in diverse climates (McKenzie et al., 2004). An intricate mosaic of soil formation times is therefore the rule rather than the exception in most areas with Mediterranean climate. The rapid development in recent years of techniques for dating surfaces and deposits (e.g. cosmogenic nuclides; optically stimulated luminescence) has made it possible to determine the ages of soils, and therefore better constrain the time factor in soil development at a pace that was unthinkable a couple of decades ago (Watchman and Twidale, 2002).

Soil-forming processes

Mass additions and losses

The strong influence of water erosion results in marked catenary differentiation in mountainous and hilly areas. Thin, occasionally skeletal soils on the upper part of the slope give way to increasingly thick soils as the footslope is approached. Increasing thickness is usually associated with increasing textural fineness and with changes in the mineralogical assemblage of the clay fraction.

Most Mediterranean areas lie at the fringe of deserts (e.g., the Sahara, Mojave, Atacama, Great Victoria, Namib and Negev deserts). This has resulted in more or less frequent episodes of eolian dust addition. Direct measurement of the dust carried by 'mud rains' and detailed mass balances in soils close to the Mediterranean sea have yielded or supported figures of a few grams per square meter and per year. Dust accretions, gradually assimilated by the soil during the Quaternary, may account for up to 50% of the mass of some soils. In the Mediterranean region the textural classes of eolian deposits of silty textures are assimilated into the classic definition of loess soils, nonetheless coars silt and fine sand are also present (Coudé-Gaussen, 1990). The deposition of atmospheric dust must be considered as an important factor in the formation of certain Mediterranean soils, such as Terra rossa (Yaalon, 1997).

Leaching and redistribution of calcite and silica

Weak-to-moderate winter leaching enables weathering of silicates and significant translocation of basic cations. Thus, mature soils that developed on base-poor parent materials exhibit acid pH values in the surface horizons, with pH and base saturation generally increasing with depth. If the parent material contains calcite, dolomite, or Ca-rich weatherable minerals and winter leaching is scarce to moderate, Ca precipitates as secondary calcium carbonate (in the form of calcite) in some soil horizons. Calcic horizons with carbonate nodules of different forms and sizes occur in soils in areas with $P < 700\text{--}800\text{ mm}$ and are replaced by indurated calcrete (petrocalcic) horizons where $P < 400\text{--}500\text{ mm}$. Long stretches of the dry Mediterranean areas (e.g., La Mancha region in central Spain) are covered by soils with calcrete (Torrent and Cabedo, 1986). The depth at which carbonate accumulates is a function of not only the climate and parent material, but also relief and, particularly, time (Fig. 2). Additionally, palustrine calcretes also develop in lowlands of semi-enclosed drainage basins, constituting what the literature describes as azonal soils. Based on ages obtained by absolute dating, the formation of calcrete takes several tens of thousands of years to reach its most advanced stages. While Ca-rich

Fig. 2 Depth distribution of CaCO_3 in soils of a river terrace sequence (Henares River, central Spain). Numbers denote relative soil age (1, recent alluvium; 6, highest terrace). soils are widespread in the Mediterranean region and some areas of South Africa and Australia, these are not as common in the Mediterranean areas of Chile and California.

While silica and mixed silica–carbonate horizons are less abundant than carbonate accumulations in the Mediterranean basin, they are present in all other Mediterranean areas with their distributions being remarkable in some areas of Australia and South Africa. The release of silica is favored by weathering of volcanic materials or a large presence of sodium additions by rain, fog or dust. Silica is slightly soluble at pH above 8.5, and it is translocated during winter and precipitated as hydrated amorphous silica (opal) in the form of nodules or crusts (duripans) during the summer. Its presence is associated with old stable land surfaces in dry areas with a winter rainfall patterns. Examples of this are the San Joaquin duripan in California of fluvial origin, the durbank soils of South Africa, where marine spray plays an important role, and the deeply weathered landscapes of southwestern Australia, where in many cases they preserve old surfaces from erosion (Torrent et al., 1980b). In Australia silcretes or duripans can be the result of many cycles of landscape and soil formation over millions of years under different climates.

Clay translocation

Clay translocation (illuviation) has been, and continues to be, a major process in the genesis of Mediterranean soils, particularly in the more humid areas and periods. Because of the strong flocculating effect of polyvalent cations like Ca or Mg, decalcification is required for clay particles to disperse and be carried by percolating water; however, translocation of clay has occasionally been observed in calcareous soils. Summer drought seems to favor clay translocation, probably because, when the soil dries, cracks develop and clay on the freshly exposed surfaces is easily dispersed and transported by the water percolating after the first autumn rains (Sauer, 2010). Clay translocation is generally a slow process, but soils with horizons rich in illuviated clay (argillic horizons) have formed within 2000–3000 years on the alluvium of some rivers of Spain. However, well developed argillic horizons with notable clay films could take over 50,000 years to form under Mediterranean climate conditions. Summer drought generally contributes to disruption of the clay cutans resulting from clay translocation (Fig. 3). Thus, evidence for clay translocation is provided by the presence of undisturbed cutans in deep soil horizons, or by the increase in the fine-to-total clay ratio with increasing depth (Fig. 4), since the fine clay particles are assumed to be more mobile than the coarse ones (Torrent et al., 1980a).

Rubefaction

Rubefaction (i.e., reddening due to pedogenic hematite formation) is quite common in the Mediterranean region. It follows decalcification because the high pH of calcareous soils hinders weathering and Fe release from primary minerals. Mediterranean climate conditions are particularly favorable for hematite formation, as during winter there is sufficient moisture for Fe to be released by weathering. Iron precipitates as ferrihydrite, which is dehydrated and transformed to hematite during the dry and warm Mediterranean summer. Appropriate environmental conditions for the formation of hematite from ferrihydrite include a high temperature, dry conditions, low organic matter content, near-neutral pH, and large concentrations of Ca^{2+} and Mg^{2+} . In the absence of one or more of these conditions, goethite (a yellow Fe oxide) is formed (Sauer, 2010).

Fig. 4 The increase with depth in the fine-to-total clay ratio in two deep soils of southern California is taken as evidence for clay translocation. Data from Torrent J, Nettleton WD, and Borst G (1980a) Clay illuviation and lamellae formation in a Psammentic Haploxeralf of Southern California. *Soil Science Society of America Journal* 44: 363–369; and Torrent J, Nettleton WD, and Borst G (1980b) Genesis of a Typic Durixeralf of southern California. *Soil Science Society of America Journal* 44: 575–582.

The vivid red hue of some Mediterranean soils has attracted the attention of pedologists, geologists, naturalists, and travelers. Terms such as the Italian ‘Terra Rossa’ or ‘red Mediterranean soils’ have been incorporated into some classification schemes and used (and abused) by pedologists to denote different red-colored Mediterranean soils. Indeed, pedogenic hematite possesses a strong pigmenting power, so a concentration of more than 10 g kg^{-1} soil often results in reddish brown or redder hues. Redness ratings derived from the Munsell color notation and the soil hematite content are well correlated (Fig. 5).

Soil chronosequences indicate that rubefaction and clay illuviation develop at similar rates once the upper soil horizons have been decalcified. These three processes play a crucial role in soil development on stable geomorphic surfaces. This is shown in Fig. 6, which depicts an idealized development sequence on calcareous alluvium under an ‘average’ Mediterranean climate. Soils comparable with members of this sequence are present on widely different parent materials that range from hard igneous rocks to unconsolidated sediments. Two related development sequences must be considered here. One has soils with no carbonate

Fig. 5 Relationship between a redness rating derived from the Munsell color notation and the hematite content in a group of Mediterranean soils. Data from Peña F and Torrent J (1984) Relationships between phosphate sorption and iron oxides in Alfisols from a river terrace sequence of Mediterranean Spain. *Geoderma* 33: 283–296; Torrent J and Cabedo A (1986) Sources of iron oxides in reddish brown soil profiles from calcarenites in southern Spain. *Geoderma* 37: 57–66.

accumulation, so it must be assigned to base-poor rocks. In the other, the old soils exhibit a seasonally perched water table that develops as a result of pore clogging by illuviated clay. In this case, redoximorphic features appear and the red hue is lost due to reductive hematite dissolution.

Development of vertic features

The xeric regime favors development of the vertic features typical of Vertisols and other clayey soils that usually experience several major shrink–swell cycles each year. Vertic features seem to develop over short pedogenic times in clayey sediments as recent alluvium or Tertiary marls. Furthermore, vertic features are enhanced by smectite formation in the soils of footslopes and closed basins as a result of lateral illuviation of silica and bases. For this reason, Vertisols occupy the lowest topographic positions of some Mediterranean soilscapes, even though the parent material may not be clayey.

Major soil types

Many pedologists would subscribe to the idea that the Mediterranean climate dictates the predominance of some specific soil-forming processes and thus justifies the term ‘Mediterranean soils.’ However, pedodiversity is probably higher in the Mediterranean region than in any other climatic zone (Ibáñez et al., 2013; Ibáñez et al., 1998). How can these two conflicting views be reconciled? Probably by remembering that: (1) the Mediterranean climate encompasses a rich variety of subclimates and (2) the effect of the Mediterranean climatic and biotic environments is modulated by the considerable lithological and geomorphic diversity resulting from the complex tectonic and climatic history of Mediterranean regions.

Various classification schemes have been used – some only at the national level – to encompass the Mediterranean pedodiversity. Some of the older schemes incorporated geographical and color terms (e.g., ‘Black Andalusian Earths’) with somewhat diffuse definitions. Most pedologists have by now adopted the FAO *World Reference Base for Soil Resources* and the Soil Taxonomy System developed by the Soil Survey Staff of the United States Department of Agriculture (USDA). The latter is used here for a cursory description of the main soil types.

Eleven of the 12 orders in Soil Taxonomy are represented in the Mediterranean regions. Soil orders in decreasing area of coverage are Entisols, Aridisols, Inceptisols, Alfisols, Mollisols, Andisols, Vertisols, Spodosols and Ultisols. While Histosols and Oxisols are rare and very localized (Fig. 7).

Entisols are widespread in all Mediterranean regions, with an important presence in Mountainous areas and young fluvial deposits along the Mediterranean basin, and in dune fields in South Africa and Australia. Entisols, which exhibit minimal pedogenic alteration, are particularly abundant in the mountainous or hilly areas where water erosion and other mass-wasting processes keep the soil permanently thin. These soils are usually classed as Xerorthents. Less abundant, but agriculturally important, are Xero-fluvents, which occupy alluvial plains and some colluvial areas. Psamments (sandy Entisols) are confined to alluvial, coastal dunes, and sandy continental deposits, and Aquents (wet Entisols) are confined to some depressions, deltas, and alluvial flats. It is quite common for the soils of these two suborders to underlie ecologically significant rather than agriculturally valuable areas.

Photograph credits: A, C and D Jorge Mataix-Solera; B, E and F, Marco Pfeiffer.

In contrast to what was previously thought, Aridisols cover vast areas in the driest parts of the Mediterranean regions with an important presence in North Africa and Australia. In total, they cover about a quarter of the areas with Mediterranean climate. The suborder Calcid is the most common and it usually occupies flat to undulating plains. They can form from weathered limestone rocks, eolian blown and lacustrine sediments. Calcids also can occur at different stages of development from carbonate masses at calcic horizons to well-developed petrocalcic horizons forming calcretes. Argids, tend to form on the old stable geomorphic surfaces and they are mostly attributed to wetter paleoclimates that allowed clay illuviation. Occupying much smaller areas, Cambids can be locally important for agriculture. Gypsis, Cryids and Salids are not abundant, however the latter frequently host ecologically unique areas in deltas, enclosed depressions, and coastal plains.

Inceptisols in Mediterranean areas often represent steps in evolutionary sequences ranging from raw soils (Entisols) to Alfisols or Vertisols, but they are truly mature soils in other cases. Most are Xerepts, but Udepts, Ustepts and Aquepts are also present to a limited extent. Xerepts include soils with calcic or petrocalcic horizons (Calcixerpts) and acidic soils (Dystroxerepts). They occur in all types of landscapes and climatic areas, and include agricultural and forest soils. Aquepts are restricted to alluvial and coastal plains, and closed basins; in addition, like Aquents, some are environmentally significant and can be turned into good agricultural soils after drainage.

Alfisols are widespread and correspond to most of the development stages of the chronosequence in Fig. 6 (and similar chronosequences). Alfisols are generally found on stable geomorphic surfaces over a wide variety of parent materials and are represented by the Xeralf, Ustalf and Aqualf suborders. Aqualfs are locally significant in depressions, closed basins, and plateaus, and they tend to exhibit a perched rather than a permanent water table. Among the Xeralfs, Durixeralfs (with duripan) are generally restricted to volcanic areas, and Fragixeralfs (with fragipan) and Plinthoxeralfs (with plinthite) are relatively rare. Rhodoxeralfs, which have vivid red colors, are commonplace – but not so much so as the Haplo- and Pale-xeralfs – and cover a variety of well-drained parent materials (calcarenes, hard limestones, arkoses, sandstones, colluvial of acid rocks, basalts, etc.). Terra rossa

sensu stricto (i.e., a red, clayey soil on pure, hard limestone) generally belongs to the Rhodoxeralf group. Reddish-brown Xeralfs not meeting the stringent color requirements for Rhodoxeralfs are also commonplace and are generally classed as Haploxeralfs. Palexeralfs ('old' Xeralfs) generally occupy old geomorphic surfaces such as higher river or marine terraces and ancient pediments. Some possess a petrocalcic horizon; others tend to support a perched water table. Haploxeralfs, however, which are regarded by many as the 'ragbag' of Xeralfs, constitute the most widespread great group.

The presence of a dark, well-structured (Mollic) epipedon (a requirement for the Mollisol order) was probably common at some time under the typical sclerophyllous vegetation. Man's activities (deforestation, plowing, grazing, etc.) have resulted in substantial losses of organic matter and deterioration of the good structural properties of the epipedon. Assessing the extent of such changes, however, is a difficult task. At present, less than 10% of the Mediterranean region is covered by Mollisols (mostly Xerolls), which tend to be concentrated in mountainous areas, man-made grasslands, and other uncultivated areas.

Andisols are mostly present in Italy and Chile (Xerands) and are located in areas where intense volcanic activity meets the climatic conditions that allow the process of andosolization to happen, namely the formation of allophanic nanominerals and Al-humus complexes. In flat areas, these soils play an important role in agriculture as they have very good physical and chemical properties. In areas with steep slopes Andisols are at high risk of landslides due to their particular mechanical/thixotropic properties.

Vertisols form readily where the parent material is clayey or the local conditions favor the formation of smectite. Mediterranean Vertisols (Xererts) occupy relatively large areas on Tertiary marls and Quaternary clays (e.g., in the Guadalquivir river valley in Spain and some plains of western Morocco, where smectite is largely inherited from the parent material ('lithogenic' Vertisols)). In closed basins, footslopes, and some poorly drained areas, where smectite is neoformed ('topogenic' Vertisols), Xererts alternate with Aquerts and gradually merge into Alfisols at some higher topographic locations. Among Xererts, Calcixererts are probably more abundant than Haplo- and Duri-xererts, because the low hydraulic conductivity hinders decalcification in Vertisols.

Ultisols exhibit low base saturation in the subsoil, so they can rarely develop under the rainfall regime imposed by the average Mediterranean climate. However, they do occur in areas where at least two of the following conditions are met, namely: (1) high (more than 200–300 mm) winter leaching; (2) base-poor parent materials (e.g., slates or quartzites); and (3) a stable geomorphic surface. These three conditions are fulfilled, for instance, by Xerults and Aquults in Pliocene *raña* formations, which occupy more than 10,000 km² in Spain. They are generally associated with Ultisols on these old surfaces, soils with plinthic properties appear sporadically, and even bauxites. The presence of Nitisols has also been documented. Many of these began to form in the Pliocene and have undergone various climatic changes over time, which is why we can speak of polycyclic paleosols.

Finally, only the coincidence of unusual local conditions favors the occurrence of Spodosols, Andisols, and Histosols. For instance, Spodosols in western Portugal form on coastal dunes under pine forests in a subhumid Mediterranean environment. Leached podzols in the South African Cape Region, south Western Australia and Californian marine terraces have their location on old landscapes in common, while the particular conditions of their formation are not fully understood. Small patches of spodosols occur locally in high mountains under acidifying vegetation and humid environmental conditions, as has been reported in Spain.

Table 3 shows the probable extent for the most common soils in the Mediterranean region. These figures are only tentative, given the relative scarcity of detailed soil maps for some Mediterranean countries.

Physical, chemical, and mineralogical properties

Many areas bordering the Mediterranean have been deforested and cultivated for centuries and even millennia. Man-induced water erosion and organic matter depletion have affected extensive areas, down to unsustainable limits, i.e. badlands. Soil degradation in other Mediterranean areas has been less marked, but current risks from agriculture, forestry, industrial activities, or modern urban needs are considerable in most areas. Soil properties must be considered from the standpoint of their significance and evolution in different human-influenced scenarios, which change – sometimes dramatically – with time.

Physical properties

In general, the quality of Mediterranean soils is more influenced by physical than by chemical properties. Moreover, some physical properties cannot be greatly modified (e.g., texture) or changed without much effort (e.g., structural stability).

Mediterranean soils tend to be more clayey than soils from cool temperate areas. Textural contrasts such as those exhibited by Alfisols are common and generally result in water-holding capacity increasing with an increase in depth, which favors growth of rain-fed crops. Stoniness is widespread and generally reduces crop production; however, surface stoniness helps to reduce surface evaporation, protects soil against splash erosion, and delays runoff.

The weak structural stability of many cultivated soils has been attributed to their low organic matter content. Various studies, however, have revealed other factors (Fe oxides, Ca saturation, clay type) to be equally important with a view to creating good structure. Soil crusting affects many soils rich in silt and fine sand, where it hinders the emergence of small seedlings and triggers runoff. Hardsetting A horizons, which combine structural instability and high strength when the soil is dry, have been reported in the Xeralfs of Southwest Australia and some countries bordering the Mediterranean.

Low water availability in summer limits the yield potential of Mediterranean soils, even though they possess, on average, a water-holding capacity exceeding that of soils in humid temperate regions. Soil crusting and poor infiltration may offset the latter advantage, however.

Table 3 Soil types most commonly found in Mediterranean areas.

<i>Order^a</i>	<i>Suborder^a</i>	<i>Group^a</i>	<i>WRB^b</i>	<i>Probable extent (%)</i>

Mineralogical properties

The lack of coincidence of high temperatures and high moisture contents prevents intensive weathering in the Mediterranean environment. Therefore, highly weathered soils occur only on old, stable geomorphic surfaces in subhumid regions. Generally, because of the low-to-moderate degree of weathering, many of the silicate clays are inherited from the parent material, or produced by transformation of primary micas rather than neoformed from solution. Illite comprises approximately 50% of the clay fraction on average, as it abounds in sedimentary rocks and is produced by the transformation of muscovite.

The overall sequence of abundance of clay minerals is illite > smectite, illite–smectite mixed-layers > kaolinite > chlorite, vermiculite, hydroxy-interlayered vermiculite >> halloysite, palygorskite, pyrophyllite, talc. The composition of the soil solution in many soils falls near the lines bounding the kaolinite and smectite stability fields. There is indeed evidence that kaolinite in the more leached soil environments and smectite in solute-rich environments are neoformed in substantial amounts. Neo-formation of illite has been documented in K-rich solutions, such as those in the microcracks of potassium feldspar grains. The presence of different microenvironments, leaching gradients in the soil profile, and lateral eluviation combine to create differences in clay mineralogy with depth and along *catenas*. Fig. 8 depicts an idealized spatial distribution of the minerals present in the clay fraction along a typical catena.

Iron oxides are the most abundant among non-silicate clay minerals; they typically account for 5–10% of the clay fraction. The Mediterranean pedoenvironment favors crystallization of ferrihydrite to goethite and hematite, so that the ratio of poorly crystalline to crystalline Fe oxides is generally low. Aluminum oxides are rare, but gibbsite is present in some excessively drained soils formed on coarse-grained, acidic plutonic rocks.

Among the abundant carbonates, calcite and magnesium calcite are either inherited or secondary, whereas dolomite is always inherited. Calcite crystals can be dispersed in the soil matrix or aggregated in nodules, tubules, or crusts. Crystals range in size from clay to fine sand, but the fine silt fraction is generally the most abundant.

Chemical properties

The pH of Mediterranean soils generally lies within the slightly acidic to moderately alkaline range and, because of the occasionally steep vertical leaching gradient, it can increase substantially with depth. Thus, the idealized mature soils of Fig. 6 typically have a pH

Fig. 8 Relative abundances of silicate clays in the clay fraction of soils of a hypothetical catena on a granodiorite saprolite in a typical Mediterranean environment. K, kaolinite; I, illite; V, vermiculite; S, smectite.

of around 6 on the surface and around 8 in the horizons where carbonate accumulates. However, plowing and accretion of dust from nearby or distant sources often result in recalcification of surface horizons. Consequently, the highly acidic soils formed on old geomorphic surfaces from acidic rocks are usually far from areas with calcareous soils and rocks.

The characteristic mineral assemblages of Mediterranean soils endow them with interesting quantitative adsorption features. Thus, the cation exchange capacity of the clay fraction generally ranges from 40 to 60 $\text{cmol}_c \text{ kg}^{-1}$ as a result of the prevalence of 2:1 clay minerals. Specific ion adsorption by hydroxylated mineral surfaces largely arises from Fe oxides and, to a lesser extent, from the edges of clay minerals and aluminum oxides. Calcite surfaces also play a prominent role in adsorption and heterogeneous precipitation processes. Quantitative relationships between adsorption capacity and simple mineralogical or chemical properties can be established for most of the inorganic adsorbates of interest (e.g., phosphate).

In general, the adsorptive properties of Mediterranean soils depend strongly on depth as a result of steep gradients in pH, particle-size distribution, and mineralogical composition. Consequently, the appropriate 'filters' for the different nutrients and pollutants lie at different depths – and make morphological and mineralogical characterization of the soil profile necessary.

From the standpoint of chemical fertility, Mediterranean soils compare favorably with soils in other geographic areas. After N, P is the most limiting nutrient in native soils; fortunately, most soils are acceptably responsive to fertilization with P. Most soils are well supplied with K, because of the high illite content, and contain adequate levels of Ca and Mg. However, Fe, Cu, Mn, Zn, and B deficiencies frequently arise in some horticultural crops cultivated on calcareous soils.

Salinization, occasionally accompanied by specific ion toxicity problems, has made its way in both old and recently irrigated areas. Even though the principles for good management of irrigation have been known for decades, salinization continues to be a major issue; the scarcity of good irrigation water in most areas, and the use of water-saving irrigation systems, contribute to the problem.

Main threads

Mediterranean regions suffer from environmental pressures that mainly derive from its greatest attribute: their privileged climate makes them attractive places to settle as well as for the development of agriculture. Most Mediterranean areas have suffered from long and intensive exploitation for agriculture, which competes with human settlements for fertile soils. The rapid population increase over the last Century has resulted in a continuous loss of natural areas and fierce competition for the scarce soil and water resources of these areas. In addition to this, human impacts in Mediterranean regions are accentuating the effect of climate change through resources capture, intensive land use change, soil degradation and an increasing occurrence of forest fires.

One of the biggest challenges that threaten these particular climatic regions is a substantial decrease in water availability, as reports indicate that climate change will dramatically affect the water balance through an increase in temperature (and therefore evapotranspiration) and decrease in precipitation (Deitch et al., 2017; IPCC, 2013). These will place increased stress on ecosystems and increase the conflict between water users. This together with increasing land degradation because of poor soil and water management, a decrease in soil organic carbon, salinization of water and depletion of aquifers among other factors (Ryan et al., 2006) could directly impact local populations. These factors could also affect access to good quality drinking water and food security through the increase in production costs and the moving away from cultivation to urban activities.

Abstract

Soil formation in arid and semi-arid regions is dominated by physical processes and largely determined by available water. Moisture enters and leaves mainly at the soil surface, which leads to incomplete leaching and precipitation of secondary minerals. Soil types are characterized by initial or weak soil development, and parent materials often comprise a significant proportion of aeolian sediments. Dust fixation processes play a role for soil properties because aeolian sediments may be partly re-mobilized. If sufficient water is available, soils can be fertile as base saturation can reach 100%. Soil quality is dominated by physical properties such as particle-size distribution.

Key points

- Soil formation in arid and semi-arid ecosystems is governed by physical processes
- Deep and intense soil formation is rare due to minimal chemical weathering
- Soils are characterized by soil types with initial or weak soil development
- Dust and aeolian sediments contribute significant proportions of parent materials and may create deep soil covers (desert fringe loess)
- Sediment fixation processes play a role for soil properties because aeolian sediments may be partly re-mobilized
- Soils in desert fringes have been used agriculturally since earliest civilizations and can be very productive under well-adapted land use strategies

Introduction

About 30% of the earth's land surface is covered by arid and semi-arid areas (Monger et al., 2005). Due to the unfavorable climate causing a lack of water, human land use and settlement are of limited size and restricted to relatively small parts of this area. Drylands are considered important land reserves for future generations which can be utilized if sustainable, well-adapted land use strategies that address the restricted resources are developed and applied. Arid and semi-arid areas are usually covered by sparse vegetation, and the intensity of soil development is confined accordingly. Many soils in drylands are shallow, stony, or affected by high salt concentrations. This is reflected by the main characteristic soil types, which indicate limited soil development (Table 1). However, despite these natural limitations, desert fringes host the oldest agricultural soils of the world which were intensively used by ancient civilizations. In this context, deep and very productive soils of aeolian origin are present in some areas, mainly at the transition of semi-arid to arid climate (desert fringe loess). Their origin and formation are still debated. This also applies to clay-rich soils on limestones (mostly of reddish color: Terra rossa), which dominate many areas of semi-arid (Mediterranean) climate in the subtropics.

Table 1 Prevailing soil types in arid and semi-arid climates of the subtropics and tropics according to Soil Taxonomy (USDA, 2014) and World Reference Base of Soil Resources (WRB, 2015).

Climate zone	Soil Order (USDA)	Reference Soil Group (WRB)	Description
Arid	Entisols	Leptosols	Weakly developed soils, either very shallow (Leptosols) or without characteristic pedogenic horizon development (Regosols)
		Regosols	
	Aridisols	Arenosols	Soils with aridic (i.e., dry) moisture regime, weak soil development, often enrichment of calcium carbonate and/or gypsum or other salts
		Solonchaks	
		Gypsisols	
Semi-arid	Inceptisols	Calcisols	Moderately developed soils, often of reddish color, with clay-rich B-horizon, and frequently rich in primary or secondary calcium carbonate
		Cambisols	
		Calcisols	
	Vertisols (Alfisols)	Vertisols	Deep cracking soils, often of reddish color, with high clay content. Vertisols shrink and swell with moisture variations (mixing the solum), whereas Alfisols and Luvisols are characterized by clay maxima in the subsoil due to clay illuviation (rare in drylands)
		(Luvisols)	

Climate: Definition and significance for soil development

Arid regions are commonly understood to receive less than 250 mm of mean annual rainfall, whereas semi-arid areas receive between 250 and 500 mm. The terms desert and steppe are used to describe such arid and semi-arid lands, accordingly. However, precipitation alone is insufficient to determine how much water is available to plants. Therefore climate classification systems, such as the Köppen–Geiger system, include mean annual temperature as a second property (Peel et al., 2007). The consideration of precipitation in the context of temperature leads to different demarcations of desert and steppe areas depending on the type of precipitation, e.g., summer or winter precipitation, because subsequent evapotranspiration depletes soil moisture to a larger degree during summer than during winter (Fig. 1).

However, climate zone classifications based on temperature and precipitation are useful only on large spatial scales. Variation at scales <100 km, in particular in transitional areas, are usually not reflected by these systems. Therefore, potential evapotranspiration (PET) has been used with mean annual precipitation P to calculate an aridity index P/PET (UNESCO, 1979). However, PET is not

Fig. 1 (a) Climate categories based on mean annual precipitation. (b) Desert and steppe boundaries as a function of both mean annual precipitation and temperature according to the Köppen–Geiger system. Arrows show how boundaries shift according to whether precipitation falls mainly in the summer or winter. From Monger HC, Martinez-Rios JJ, & Khresat SA (2005) Tropical soils. Arid and semi-arid. In Hillel D (Ed.) *Encyclopedia of Soils in the Environment*. 1st edn, pp. 182–187. Amsterdam: Elsevier, 183, Fig. 1.

easily determined as most meteorological stations do not systematically record all properties needed for its calculation. The Penman approach to calculate PET, for example, includes net solar radiation, wind speed, and humidity of the air.

The Thornthwaite approach is a simplified method to calculate PET and is based on only two variables: mean monthly temperature and average number of daylight hours per month. It has been applied to the Negev desert in southern Israel and enabled sub-division of the area into semi-arid, arid, and hyper-arid parts, whereas the Köppen–Geiger system characterizes the whole region uniformly as arid (B)¹ (Bruins, 2012). The more detailed subdivisions based on P/PET are very important for any assessment of land use and soil development because effective soil moisture is more significant to vegetation than annual precipitation and temperature alone. In addition, soil water potential includes the effect of particle-size distribution and salts, which may lead to locally varying soil development processes. Therefore it is difficult to predict or assess soil development or land use potential in drylands solely on the basis of climate classifications.

Processes of soil formation

Jenny (1941) outlined how soil formation is a function of five main factors:

- (1) climate
- (2) organisms
- (3) topography
- (4) parent material
- (5) time

These interact in specific ways to produce arid and semiarid soils (Fig. 2). Climate determines water supply and is therefore the most relevant factor. Water governs mineralogical transfers and transformations, and is essential for vegetation, both with regard to direct use and nutrient supply. (Monger et al., 2005) Vegetation translocates ions by root transfer and bioaccumulation, adds organic matter, and provides ground cover and roots which protect the soil from erosion. Furthermore, vegetation feeds animals which catalyze seed dispersal and affect soils by bioturbation.

The limited availability of water means that nearly all moisture in arid soils and much in semiarid soils enters and leaves via the soil surface. Only in specific topographies, that is in low-lying areas which receive runoff water (e.g., playas or runoff-irrigated terraces), can water permeate to deeper parts of the soil profile. Such soils are mostly not saline if the water table is deep and if the soils have good permeability, because leaching prevents the accumulation of salts. However, salts accumulate in depressions where soils have low permeability (e.g., if clay contents are large or when compaction has occurred), or where shallow groundwater tables are present (typically leading to the presence of salt pans). If a capillary bridge to shallow groundwater is established, evaporation will transport ions to the soil surface where they precipitate as salts and impede the growth of most plants.

Fig. 2 Illustration of the links among the soil-forming factors of climate, biota (vegetation and animals), topography, and parent material. The fifth factor, time, affects all of the illustrated links in proportion to the duration over which the factors operate. From Monger HC, Martinez-Rios JJ, & Khresat SA (2005) Tropical soils. Arid and semiarid. In Hillel D (Ed.) *Encyclopedia of Soils in the Environment*, 1st edn, pp. 182–187. Amsterdam: Elsevier, 184, Fig. 2.

¹The classification of the Negev as arid (B) according to the Köppen–Geiger System includes steppe climate BSh and desert climate BWh (where mean annual temperatures are $>18^{\circ}\text{C}$), and steppe climate BSk (where mean annual temperatures are $<18^{\circ}\text{C}$).

The movement of water and solutes is not mainly directed to the bottom of soil profiles as in humid areas, but largely toward the soil surface. Leaching is mostly incomplete which favors the precipitation of secondary minerals, such as calcite, silica, and gypsum. These accumulate in the profile, leading to the formation of calcic, petrocalcic, gypsic, and petrogypsic horizons, and of duripans (Monger et al., 2005).

With the limited amount of water, chemical weathering and dissolution of bedrock do not play a major role in arid and semi-arid soils. Rock disintegration, however, can be intense, resulting from the crystallization of salts at the rock surface and from thermal fluctuations. The detritus derived from rocks is transported by gravity, runoff, or wind and contributes to soil formation. In particular wind transport, i.e., the deposition of aeolian sediments, plays a major role in soil development of arid and semi-arid areas.

The role of aeolian sediments

Typical aeolian landscapes, i.e., landforms showing obvious formations of aeolian origin such as dunes, are relatively rare. Deserts do not always host sand dunes (Ergs), but are often characterized by a cover of rock fragments (Hammadas). Aeolian transport is nevertheless an important process of soil development and sediment deposition in most drylands.

Desert pavements

The importance of aeolian processes can be illustrated by desert pavements, which are present in many arid areas. They are characterized by a dense cover of stones and detritus at the soil surface and an accumulation of the fine fraction (mostly of silt and fine sand size, i.e., $<200\ \mu\text{m}$) below. Desert pavements have often been interpreted as the result of intense wind erosion which removed fines, originally from much larger deposits of sediments, leaving the larger size fraction in place until a dense stone cover formed that protected the remaining fines from further wind erosion.

Recent research, however, suggests that sometimes the opposite could be true: various desert pavements might be products of dust accumulation (Fig. 3). This is due to the processes of dust fixation: Aeolian sediments accumulate below stones as these provide wind shadow and preserve moisture, which contributes to the fixation of fines. Dust gathers over time at stone bottoms and is covered by surface crusts of biological and or chemical origin, i.e., formed by lichens, bacteria, mosses and liverworts or secondary minerals such as CaCO_3 (calcium carbonate). Formation of surface crusts is favored by arid conditions as evaporation leads to formation of secondary minerals at the soil surface. In addition, vegetation competes with biological crusts because plant cover reduces solar radiation and suppresses the growth of biological crusts in better-watered areas. These crusts stabilize substrates and are impermeable to air. Therefore, water entering during rain events forces soil air into gas-filled voids, expanding soil volume and creating vesicular layers. These can be found in topsoils below desert pavements. The formation of air-filled voids leads to the uplift of detritus and, over time, to the formation of stone pavements (Turk, 2012). The flat and apparently 'empty' areas in deserts which

Fig. 3 Desert pavement at the Neolithic site of Harrat Juhayra on a basalt field near Ma'an in southern Jordan. An archeological excavation trench exposes a Neolithic wall, and illustrates that silt-dominated sediments were deposited after construction of the wall, burying parts of it. The silt-rich sediments were themselves completely covered by basalt rock detritus, suggesting that this desert pavement is of the accretionary type, characterized by an uplift of the stone cover during the accumulation of fines. Person gives scale.

Fig. 4 Calcareous, silt-dominated sediment covered by detritus in a depression of sandstone rock close to the summit of a mountain near Petra, southern Jordan. GPS gives scale. Note that fine sediments and detritus are bound together by a crust developed on the surface. Such sediments are only present in areas where water gathers, illustrating the role of fixation for dust deposition processes.

are covered by desert pavements are thus landscapes largely formed by aeolian processes, either wind erosion or deposition of aeolian sediment.

The potential role of dust aggradation for the formation of desert pavements underlines the importance of sediment fixation for soil development in drylands (Fig. 4). In this context, the material moving through the atmosphere is not necessarily identical to that of the substrates of soils formed from aeolian sediments, as deposition partly depends on fixation processes. Biological crusts, for example, have been found to fix particles of silt and clay size (Danin and Ganor, 1991), but not sand, which might subsequently be re-mobilized.

Desert fringe loess

Transitional areas between the semi-arid and arid ecozones are sometimes covered by deep, silt-dominated soils, which have properties very similar to loess. Most of them formed during the Pleistocene. However, as no nearby glaciers are known that could have produced the silt dominating the substrate, the origin of these soils is debated. The discussion focuses largely on the sources of silt that could have provided the parent material of desert fringe loess. One theory that has received much attention is that abrasion of moving sand dunes might produce silt-sized particles, including quartz. This could resemble the main parent material of desert fringe loess as many of these soils are downwind from Ergs (Smalley and Vita-Finzi, 1968). Smaller abrasion sediments that were transported further may have contributed to soil development in the semi-arid ecozone (Crouvi et al., 2018). Soil formation could therefore have corresponded to specific meteorological conditions, for example, high wind speeds at some time during the Pleistocene.

Loess deposits, however, are often older than the Ergs which presumably produced their parent material (Roskin et al., 2011). In addition, they are also present in areas not located downwind from Ergs. In this context, various other processes such as fluvial comminution, insolation weathering, salt weathering, volcanism, frost shattering, and deep weathering of saprolite can produce silt-sized detritus. In particular flash floods, which frequently occur in drylands after erratic but intense rains, can lead to substantial abrasion of silt-sized material. Fluvial comminution was found to be the most effective short-time process of silt production, even more effective than glacial grinding (Wright et al., 1998). Therefore, the formation of desert fringe loess might be less a question of parent material, as silt-sized aeolian sediments are omnipresent in drylands, but of the fixation of this material.

Similar to desert pavements, it might be the presence of sediment-fixing agents such as vegetation or crusts in soils that allow aeolian sediments to settle, and prevent re-mobilization (Lucke and Bäuml, 2021). Therefore, properties of the resulting soils might partly reflect sedimentation and fixation processes, which can be illustrated with analogies to dust collectors. Depending on design, artificial dust collectors harvest different components of the material moving through the air. For example, wet samplers were found to collect more clay-sized material than dry collectors. Similar mechanisms could act in natural soils and explain why, for example, aeolian sediments in archeological ruins in the Negev desert and the desert of southern Jordan were found to be statistically similar (Fig. 5). It was possible to model them as one typical deposit, although sediments in Jordan were characterized by more sand contributed from nearby sandstone rocks which are absent in the Negev. Desert fringe loess might therefore be mainly a product of enhanced sediment fixation, possibly connected with specific meteorological conditions such as snowfall, and not to certain dust sources (Lucke et al., 2019).

(2021) Holocene dust dynamics archives in archaeological ruins in arid and semi-arid environments in the Southern Levant. *Arabian Journal of Geosciences* 14(23): 1–15, Figs. 7 and 8, p. 8, edited, CC-BY.

Aeolian transport

Identifying and discriminating between sources of global dust transport, and estimating their contribution to soil development, has been a major research question with important implications for various fields of geosciences. Satellite images have made observations of dust plumes possible, showing that deserts, and in particular the Sahara, are major sources of aeolian sediments. Saharan dust was found to have contributed significantly to soil development in remote areas (Muhs, 2013). Although the main trajectories of dust transport are well known, identification of major source areas, for example, inside the Sahara, remains difficult (Goudie and Middleton, 2001). This is connected with the rather erratic aeolian transport of particles, which depends on the changing situation of the ground surface and the occurrence of sufficient wind speeds. In addition, local dust sources may include re-mobilized older dust deposits, which can partly consist of remote material, or which might be (pre-)weathered to a certain extent before re-mobilization and subsequent deposition.

Grains are transported according to their size and weight: sand moves a few hundred meters, but silt is carried high into the atmosphere. Clay-sized particles remain in suspension in the atmosphere until washout takes place. Most of the dust that is transported over long distances consists of these clay-sized particles, which are permanently present in the high atmosphere over deserts. Sometimes 'giant' sand-sized particles have been transported over long distances of thousands of kilometers, but the reasons for this phenomenon are so far unknown.

To overcome obstacles in the identification of dust sources, some studies have focused on suspended dust in the atmosphere, assuming that it comprises mainly material transported from distant sources. But samples collected in Israel had the same mineralogical and chemical composition of dust particles from several synoptic conditions that carry desert dust. The variable aspects were somewhat larger amounts of palygorskite and Mg in dust that originated from the Arabian deserts (Kalderon-Asael et al., 2009).

Local, regional, and remote sources play a role in the composition of the silt and clay fractions (i.e., of material $<63 \mu\text{m}$) of aeolian sediments. Mixing of particles occurs with distance, and the variability of single dust storms obscures the contribution of individual sources. Aeolian transport homogenizes the material: the longer sediments remain in suspension in the atmosphere, the more difficult it becomes to discriminate sources. Sampling is also a challenge because the type of dustfall plays a role in dust composition. Samples collected during wet dustfall (rain and, even more pronounced, snow) in the southern Levant showed enrichment by calcareous silt, and also enhanced presence of most major and trace elements compared with samples from dry dustfall (Lucke et al., 2019). It seems possible that this is connected with coatings of suspended clay-sized particles on calcareous silt particles (Mahowald et al., 2014), which essentially means that larger particles may 'harvest' suspended dust during wet dustfall events.

Aeolian sediments and soil formation in semi-arid regions

Chemical weathering and thus in-situ pedogenesis might alter aeolian sediments after deposition in semi-arid areas, which adds to the complexity of identifying the contributions of parent material from remote sources. In this context, many limestones under (Mediterranean) semi-arid climate are covered by clay-rich soils of reddish or reddish-brown colors (Chromic Cambisols according to WRB (2015), or Chromoxererts or Xerochrepts according to Soil Taxonomy (USDA, 2014), but better known as Terra rossa or Terrae calcis according to older classification systems). The origin and genesis of these soils is debated: the two main hypotheses are that they are mainly derived from insoluble bedrock residue (i.e., clays trapped by the growing reefs that later formed the

limestones), or that they mainly represent long-range dust transport. The main argument against the bedrock dissolution theory is that the limestones contain very little insoluble residue, requiring vast amounts of limestone to be dissolved over long periods. In this context, available ages from the southern Levant suggest formation mainly during the Late Pleistocene (Crouvi et al., 2018), which is relatively young and contradicts an origin from bedrock dissolution. Available geochemical data supports the notion that a remote dust fraction must have contributed to soil development, but a contribution from local rocks was also evident. Exogenous grains of medium sand size were found in hilltop soils. Nearby rock outcrops on valley slopes could be identified as sources of these grains which suggests that this contribution from local rocks might have occurred largely in the form of aeolian sedimentation. As significant energy is necessary for the aeolian uplift of such large grains, their deposition was possibly associated with major storm events. This is supported by reconstructions of transport and deposition histories from grain microsurfaces which indicate an important role of intense dust storms involved in soil formation (Lucke, 2017).

Soil colors

In arid regions with limited chemical weathering, soil colors largely reflect parent materials. These are mainly yellow and brown and dominated by iron oxides. They are inherited from parent materials, which may however include (aeolian) sediments from pre-weathered older soils.

In semi-arid regions, however, in-situ weathering might take place and apparently leads mainly to formation of hematite, which gives soils a reddish color. The preferential oxidation of iron to hematite seems to be connected with rapid dehydration during summer drought. Reddish colors were sometimes found associated with enhanced magnetic susceptibilities which could arise from the formation of maghemite as a precursor of hematite (Lucke, 2017). A transect covering semi-arid to arid soils in northern Jordan showed that soil surface colors corresponded to the current hygric gradient, suggesting that the intensity of redness in this area was connected with in-situ oxidation of iron-bearing minerals (Sahwan et al., 2021). Organic matter contents, in contrast, played no significant role for soil colors.

The limited presence of vegetation and organisms, which is connected with the lack of available water, means that organic matter contents of soils in arid and semi-arid regions are small (usually <1%). Soil colors in drylands are therefore in general not related to vegetation and organic matter. This is also true for the border between Israel and Egypt, which can be identified on satellite imagery from the darker soil color in Israel, even though the geology and soils do not differ on the two sides of the border. Although measures to protect the vegetation from grazing on the Israeli side has led to a substantial recovery of shrub vegetation, the main reason for the difference in reflectance spectra seems to be the widespread, undisturbed presence of biological crusts on soil surfaces in the Israeli Negev (Tsoar et al., 1995).

Soil fertility, land use, and desertification

Soil fertility

Base saturation in most arid and many semi-arid soils can reach 100% because of limited leaching. This means that in contrast to humid soils, lack of cations is usually not a growth-limiting factor for plants. In fact, it is more likely that excess of cations (i.e., salinity) is a problem. The most frequently deficient ion is N, which is connected to the small organic matter contents. Supply of most nutrients is good provided that enough water is available for solution and transport to plants. Water availability is a limiting factor for the application of manure, as an organic fertilizer, and to an even larger degree inorganic fertilizers because they need water to become available for plants.

Physical soil properties are more important for soil fertility in drylands than chemical ones. This applies first and foremost to the soils' capacity to store plant-available water, which is why soil depth and particle-size distribution are of paramount importance. Due to small organic matter contents, cation exchange capacity is largely determined by grain sizes and depends mainly on clay minerals. This implies that many indices for assessment of soil quality or productivity that were tested and developed in temperate regions are not well-suited for arid and semi-arid regions. There, fertility assessments need to focus on physical soil properties (Husein et al., 2021). This also means that mass movements leading to erosion of topsoil are less relevant for soil degradation in drylands than in humid areas.

Land use

Semi-arid regions are the natural habitats of many plants that were domesticated for agriculture, such as cereals (*Triticum* spp.) and olives (*Olea* spp.). Domestication first took place in the Middle East during the Neolithic period some 10,000 years ago (Neolithic revolution). It was connected with the development of irrigation technologies, which also made the production of surpluses possible and led to the emergence of first civilizations. The steppes enabled rainfed agriculture, but irrigation improved yields and made expansion into arid areas possible. Rain-fed agriculture also expanded into Mediterranean forests, but probably at a later stage when fire management and metal tools were available that permitted the cutting of the often very resistant Mediterranean woods.

The Neolithic revolution induced not only domestication of plants, but also of animals which led to the emergence of pastoralism. The borders between farmers and herdsmen were probably fluid as most tribes would practice a mixed economy. Nomads who rely fully on their animals, which enables them to penetrate deeply into waterless arid areas, are a later specialized

Fig. 6 Irrigated palm groves and gardens in an oasis in south Morocco. Availability of groundwater near the surface made long-term, traditional agricultural land use possible which applies sustainable recycling of organic matter. The limiting factor of productivity is the availability of water.

development. Farming and grazing exploit different ecological niches and potentially benefit each other. In the past, the emergence and fall of civilizations has been interpreted as the 'battle between the desert and the sown,' i.e., a fight between civilized farmers and uncivilized nomads. However, it became increasingly clear that this reflects a foreign view because of lack of familiarity with the real social and economic situation in drylands. For example, archeological evidence suggests that part of the ancient civilizations' wealth was based on surpluses from pastoral land use, i.e., that some of the ancient palaces had been owned by early Bedouins. Pastoralism and agriculture were often practiced in parallel by members of the same tribal group (Lucke, 2017).

The main challenge of land use is the unpredictable water supply. For agriculture, it could be addressed by diverting water from springs and streams for irrigation (Fig. 6). In addition, rainwater could be collected in cisterns or by runoff diversion, an important technology. When sufficient water supply is secured, preventing salinization of soils is a major problem of irrigated agriculture. It is addressed by using sufficient water of good quality (i.e., not brackish or saline), and by draining excess water, which flushes out salts. Grazing of animal herds enables advantage to be taken of the spatial variation in water supply because of mobility of the animals which can move to areas with a sufficient water supply. This often follows seasonal patterns: for example, tribes in northern Jordan move their flocks eastwards to arid lands for winter pasture, and in summer to the better-watered Mediterranean areas in the west. After harvest, the grazing of stubble was a common practice that also fertilized soils. If droughts led to insufficient yields, the animals were fed on the poorly developed plants on the fields, thus still making use of them.

Agriculture even expanded to arid areas without permanent water resources, such as the Negev desert, where very fertile desert fringe loess could be cultivated. Water supply relied on runoff from the few rain events during winter time, which was diverted to terraced fields. The key to successful runoff diversion was not high average annual rainfall, but the occurrence of a few major storms that provided enough rain for the development of significant runoff. The diverted water was then stored in soils behind the terrace walls. However, only relatively small areas can be cultivated in this way, as fields need runoff collection areas about 20 times larger than the cultivated area.

These systems harvested not only water, but also aeolian sediments, and could therefore be applied even in rather hostile environments such as the arid sandstone mountains of Petra in southern Jordan (Fig. 7). There, it created fertile soils on previously barren rocks (Lucke et al., 2019). Furthermore, it reduced the risk of flash flood damage as water was diverted on a large scale at the head of the catchment, controlling flows before dangerous runoff concentrations could develop. Modern experiments in the Negev desert show that such systems could still be operated today (Evenari et al., 1971). They might be a way forward to long-term sustainable agriculture in drylands as runoff-irrigated farming can be extremely productive in years with good rainfall. The reasons for such record yields are so far unknown. However, the rather frequent occurrence of droughts and subsequent bad harvests or crop failures lead to overall mean yields comparable to rain-fed agriculture. The main disadvantage of runoff-irrigated terrace agriculture is that they require an enormous input of manual work: terraces and runoff diversion systems need to be repaired every year, while small fields do not permit the use of heavy machinery. Therefore this land use strategy currently cannot compete with world market prices of agricultural goods.

Modern technology has benefitted land use in drylands mainly by providing additional and advanced means of water provision. In contrast, advances in the field of mechanization or manure have played only minor roles due to limitations posed by the often dissected terrain, small field sizes, and lack of available water. The advances in water provision rely to a large degree on the pumping of fossil groundwater from deep geological reservoirs, which has made Saudi-Arabia, for example, one of the main wheat exporting states in the world. However, these water reserves will probably soon be depleted. The excessive use of water resources during the

Fig. 7 Remains of runoff-irrigated terraces near Petra, southern Jordan. Car gives scale. Note the small cereal plants and evidence of plowing testifying to current re-use of these installations by Bedouins inhabiting the area.

recent past has led to the deterioration of water quality, and only 'gray water' is currently available for agriculture in many arid and semi-arid regions. This is wastewater after treatment in sewage plants, which may still, however, contain harmful substances such as hormones, microplastics, or 'heavy' metals. Future land management strategies will have to develop concepts to deal with the challenges posed by these substances. If a way could be found to remove or inactivate them, this might allow the use of sewage sludge as manure, which could become a precious source of organic matter, N, and P for dryland soils.

It seems probable that non-conventional or counter-intuitive concepts will be of growing importance in the future. For example, intensive fish breeding in tanks proved very successful in the deserts of Israel, as these animals need limited water and even thrive in saline groundwater, while solar energy can be used to operate the tanks. In this context, the harvesting of renewable energy from wind and solar radiation is another promising field of future land use in drylands, provided that problems such as cleaning solar collectors from dust can be solved without excessive use of the limited water resources.

Desertification

Both variation in climate and poorly adapted land use can lead to vegetation damage and soil degradation in drylands, with the potential consequences of long-term reduced vegetation growth and diminished soil productivity. Negative impacts of climate change are mainly associated with prolonged droughts, but also excess rain that concentrates during runoff events can have adverse consequences, causing gullying for example. Poorly adapted land use is first and foremost a problem of modern practices, in particular the intense use of bulldozers, concrete construction, and the exploitation of non-renewable (fossil) water resources. When bulldozers became available, they were used to create false terraces, often at the landscape scale, or to conduct other major modifications of the natural relief. While these might be beneficial to farmers in the short term, they threaten landscape stability in the long term, aggravating the effect of flashfloods, for example (Grove and Rackham, 2003). Traditional land use such as plowing and grazing may also have negative consequences, in particular deforestation and soil erosion. With limited vegetation cover and often weakly developed soil structure, damage to plants (in particular roots) can rapidly make soils susceptible to water erosion. Plowing destroys crusts and surface cover which can trigger wind erosion.

Traditional land use in arid and semi-arid regions has been associated with Bedouins and other poorly educated inhabitants of drylands, who were sometimes considered to be the causes of desertification. However, the environmental impacts of traditional land use are smaller than modern practices, simply because it relies mostly on human and animal power and lacks modern machinery. There are also historic examples of well-managed land use strategies in drylands, such as the construction of runoff-irrigated terraces, which suggest caution with general negative assessments of traditional land use practice. The association of desertification with 'poorly developed' traditional societies could at least partly result from cultural bias (Lucke, 2017).

For more than 50 years, desertification is a topic of intense scientific debate, both with regard to defining and assessing the problem, and with regard to possible mitigation or solution strategies (Sterk and Stoorvogel, 2020). Research faces various methodological challenges, for example, determining effective numerical estimates of actual soil erosion (Grove and Rackham, 2003). Installations to record soil losses might not show any significant movements of soil for years until an extreme rainfall event hits the area. Then, again, meaningful measurements might not be possible, for example, if the remains of the installation have to be searched for and are recovered from meters of debris at the lower end of the catchment. Indirect measurements of mass movements,

Fig. 8 Camel herd grazing an *Acacia* spp. tree in the Atlas mountains of south Morocco. These animals can penetrate deeply into arid areas and feed on various dryland plants.

such as from dating sediments in depressions, can also be problematic because these might have been deposited (or re-deposited) mainly discontinuously during rare but intense rainfall events (Lucke, 2017).

Grazing, especially with flocks of goats, has often been assessed to have a general negative impact on vegetation, in particular on woody plants. It was assumed that browsing would rapidly cause overgrazing and irreversible degradation of plants and soils (Fig. 8). Animals and their herders were therefore banned from various semi-arid areas which were re-forested. However, this has sometimes made the situation worse: reforestation by tree monocultures has caused lowering of the groundwater table in some regions, while the lack of browsing of brushwood has led to an enormous increase in fire damage. Ecologically, the removal of grazing animals from forested areas has decreased biodiversity and moved the grazing pressure to more sensitive arid areas. Modern drilling of wells or moving water and herds by trucks has converted previous reserve areas (perhaps extensively grazed by camels) to intensively exploited lands. This replacement of traditional land management with its system of reserve lands by industrial land use, often been made possible only by the intense use of fossil water, has therefore sometimes caused more harm than good.

Alternative views of grazing are that in most semi-arid and arid regions, the vegetation and wild herbivores evolved in parallel and are thus adapted and interdependent (Savory and Butterfield, 2016). The impact of grazing on vegetation and soils is often quickly reversed, as many dryland plants have strong regeneration capacity and browsing does not make a significant difference to the already low organic matter contents of soils. In areas with a long evolutionary history of grazing and low net primary production, moderate grazing pressure during short time periods can result in increased vegetation growth. This is associated with some of the positive effects of limited disturbances by the animals who may act as agents of seed dispersal while their excrements supply N and P to soils. Therefore, it seems possible that historic grazing strategies mirrored to some degree the effect of browsing by wild herds, and had net positive effects for the ecosystem. This is, for example, supported by an expansion of forest in the Mediterranean areas of Jordan during periods of Bedouin domination (Lucke, 2017).

To summarize, desertification today is perceived less as a global catastrophic development, but a more local-scale degradation problem and not necessarily an irreversible process. Land use plays a crucial role as it can either stimulate or decrease degradation processes, which emphasizes the importance of long-term sustainable land use practice.

Summary and conclusion

The limited availability of water in arid and semi-arid regions largely determines soil development. Climate is the most important soil-forming factor in these areas because other factors, such as the development of vegetation and organic matter, or the development of processes linked to topography, such as runoff formation, are directly or indirectly connected with available water. However, the water balance depends not only on precipitation, but also on potential evapotranspiration (PET). The latter is linked with various other climatic properties such as solar radiation intensity, day length, or wind speed. The type of precipitation also matters, for example, whether it occurs mainly during summer or winter, and whether it is distributed in many small or few intense rainfall events. In addition, local factors such as relief, soil depth, or particle-size distribution can cause small-scale variation in moisture availability. Climate classifications are therefore useful for a first evaluation of probable soil formation on large spatial scales, but cannot be used to predict local soil development.

Moisture in arid and semiarid soils enters and leaves mainly at the soil surface. The movement of water and solutes is therefore less directed to the bottom of soil profiles, but merely toward the soil surface. Leaching is often incomplete which leads to the precipitation of secondary minerals and formation of respective soil horizons, such as secondary carbonates in calcic horizons. Due to limited chemical weathering, soils in arid and semi-arid regions are mainly characterized by soil types with only initial or weak development.

Soil formation is governed by physical processes, which can, however, be intense. Thermal fluctuation and crystallization of salts can produce significant amounts of detritus which are moved by gravity, water, and wind, and contribute to soil development. In particular, the deposition of aeolian sediments plays a major role for soil development in arid and semi-arid areas. They are both sources and sinks of dust. Although major dust trajectories can be observed on satellite images and are well-researched, it is difficult to determine specific dust sources because local, regional, and remote sources mix in the atmosphere. Local sources may also include re-mobilized, earlier aeolian sediments which may have originated from remote areas.

Because of the limited water resources, semi-arid and arid lands are largely not yet used by man and may therefore represent important reserve areas for the growing human population. Water management remains the key aspect for any successful land use in these regions, and it seems likely that non-conventional strategies such as the breeding of fish in tanks or the harvesting of renewable energies will offer future opportunities to support human life in these regions.

Future research should focus less on single variables, such as the provenance of the parent materials of dust, but more on the complexity of geomorphological processes that shape soils and landscapes in drylands. For example, dust fixation mechanisms have rarely been considered but may play an important role in the composition of soil substrates. Furthermore, dust transport in the atmosphere probably interacts with synoptic conditions and the presence or absence of precipitation, which, however, has so far remained difficult to determine. Last but not least, historic experiences of millenia of successful human land use in drylands—despite harsh and strongly changing environmental conditions, which sometimes appear hostile to life—may provide important examples for the development of future sustainable land use strategies in drylands.

Abstract

Acrisols and Alisols are found in different parts of the world and under different climatic conditions. Both soils have an argic horizon in the subsurface, although their physical, chemical and mineralogical properties are contrasting. Within the humid subtropical ecozone, these soils tend to occur mostly in hilly landscapes. This chapter focuses on characterizing Acrisols and Alisols of the humid subtropical ecozone, providing details on their properties, sites of occurrence and sustainable management systems under different degrees of management.

Key points

- Genesis of Acrisols and Alisols and their regions of occurrence within the humid subtropical ecozone are discussed;
- Differentiation of Acrisols and Alisols regarding their physical, chemical, and mineralogical properties is provided;
- Sustainable management practices are suggested for these soils to avoid soil degradation in the humid subtropical ecozone.

Introduction

Soils vary across the globe and this is mainly controlled by the five soil forming factors (climate, organisms, relief, parent material and time) and several pedogenic processes. For a better interpretation about each soil class and its importance in the environment, evaluation of soils within certain climatic conditions is necessary.

Considering all the soil types of the world, there are two somewhat similar types in the humid subtropical ecozone: Acrisols and Alisols. Both soil classes have an argic horizon in the subsurface, but the former is more weathered and leached than the latter. These soils are widely used for agriculture, although care should be taken with their management since they are susceptible to both water and wind erosion. The undulating or steeper relief on which they are commonly found, in addition to the high mean annual precipitation of the humid subtropical ecozone, make them especially prone to water erosion.

This chapter focuses on characterizing Acrisols and Alisols of the humid subtropical ecozone, providing detail on their properties, regions of occurrence and sustainable management systems under different types of management.

Brief characterization of the humid subtropical ecozone

The world has multiple combinations of climate, geology, native vegetation, altitude and relief that govern several aspects related to the environmental sciences. Each of these combinations, for example a flat area under a humid climate compared with a flat area under an arid climate, is capable of creating different conditions that control the establishment and evolution of site-specific fauna, flora, soils, and others.

For a better characterization of these different environments and their individualization regarding their ecological aspects, the so-called ecozones, also named ecoregions, have been created and defined according to the environmental characteristics intrinsic to each ecozone. Ecozones were defined by Omernik (2004) as areas that present coincident geographical phenomena, i.e., climate, vegetation, geology, soils, fauna, hydrology, physiography, impacts of human activities. According to the FAO (2012), the world is divided into 20 different ecozones, varying from tropical deserts (e.g., Sahara desert in Africa), to tropical forest (e.g., Amazonian

Fig. 1 Worldwide distribution of the humid subtropical ecozone, according to the FAO (2012).

forest in South America), temperate continental forest (e.g., central European region), and Boreal coniferous forest (e.g., parts of the northern Europe and North America continents) to name a few.

According to the Food and Agriculture Organization (FAO, 2012), the subtropical domain encompasses areas that have at least 8 months of the year with mean temperatures above 10 °C and situated between 25° and 40° of latitude. For both northern and southern hemispheres, this domain generally occupies the southeastern parts of the continents. The subtropical region is divided into five ecozones: subtropical desert, subtropical steppe, subtropical mountain system, subtropical dry forest and subtropical humid forest. In other systems of climate classification, the humid subtropical zone is classified as a type of warm-temperate climate. This chapter focuses on the humid subtropical forest zone, code SCf, which is included within humid subtropical climatic criteria, and characterized by well distributed rainfall during the whole year with all months being humid. Specifically, its mean annual precipitation is commonly greater than 1000 mm.

The native vegetation of the humid subtropical ecozone is characterized by evergreen broadleaved forests, evergreen coniferous forests, and winter-deciduous forests. Examples of vegetation types in the humid subtropical ecozone include *Eucalyptus*--*Nothofagus* (*Eucalyptus globulus* Labill. – *Nothofagus* Blume.) forests in southeastern Australia and Tasmania, *Castanopsis* (*Castanopsis* (D. Don) Spach, 1841) forests in southeastern China, *Araucaria* (*Araucaria* Juss.) forests in southern Brazil, and Longleaf-Slash pine (*Pinus elliottii* Engelm.) forests in southeastern USA. In mountainous areas of the ecozone, rainfall increases and temperature decreases with altitude. This combination of low temperature and a large amount of rainfall favors the establishment of these native forest types compared with the areas surrounding the places where such forests occur.

This ecozone is mainly distributed in southeastern USA, southern Brazil, southeastern tip of Africa, southeastern Australia, and southeastern China (Fig. 1).

Factors of formation of Acrisols and Alisols in humid subtropical conditions

The paradigm of the factors of soil formation furnishes a conceptual structure for the understanding of soil formation. One should recall that soils are formed due to the interaction of climate (cl), organisms (o), relief (r), parent material (p) and time (t), in addition to some unspecified subsidiary factors (...) that control soil formation (Eq. 1). Climate and organisms act on the parent material (material from which soils are formed, such as bedrock or mineral or organic sediments), under the influence of relief over time. Thus, the different combinations of these so-called factors of soil formation lead to the occurrence of different soil classes and with different properties across the globe.

$$S = f(\text{cl}, \text{o}, \text{r}, \text{p}, \text{t}, \dots). \quad (1)$$

Fig. 2 Occurrence of Acrisols and Alisols across the world. Adapted from FAO-UNESCO (1974) *Soil map of the world 1:5000000* Vol I. Legend, I. Rome: FAO-UNESCO.

The humid subtropical conditions mainly refer to the climate factor, but the other factors of soil formation can also vary under the similar climatic condition. For instance, by maintaining the other factors constant, variation in parent material may be the factor that determines the formation of different soil classes and properties. Different parent materials may result in contrasting soils in relation to their classification, physicochemical properties and sustainable management practices. This fact helps to explain the widespread occurrence of different soil types under the same climatic conditions. However, among the soils commonly found in areas under humid subtropical conditions, two soil classes can be highlighted: Acrisols and Alisols (The World Reference Base according to the FAO/WRB soil classification system, [IUSS Working Group, 2015](#)). These soils are equivalent to Ultisols with low-activity clays and Ultisols with high-activity clays, respectively, in the USDA Soil Taxonomy ([Soil Survey Staff, 2014](#)).

In humid subtropical regions, Acrisols are most extensive in southeast USA, the southeast tip of Africa and south Brazil ([IUSS Working Group, 2015](#)), whereas Alisols occur mostly in southeast USA and south Brazil ([FAO-UNESCO, 1974](#); [IUSS Working Group, 2015](#); [Streck et al., 2018](#)) (Fig. 2). In Brazil, these soils are found in the Paraná, Santa Catarina and Rio Grande do Sul states ([Resende et al., 2021](#)).

The climate and altitude factors under which both Acrisols and Alisols form tend in general to result in a udic soil moisture regime and a thermic soil temperature regime according to the US Soil Taxonomy ([Soil Survey Staff, 2014](#)). The udic soil moisture regime applies to soils in which the soil is not dry in the active section of the soil (2 m in these soils) for as long as 90 cumulative days in regular years. For such conditions, rainfall either has to be well distributed throughout the year (humid subtropical conditions) or there is enough rainfall in the summer so that stored soil moisture plus rainfall equal or exceed the evapotranspiration. The thermic soil temperature refers to soils in which the mean annual soil temperature is 15 °C or higher, but lower than 22 °C, and the difference between mean summer and mean winter soil temperatures is 6 °C or more.

In humid subtropical conditions with well-distributed rainfall there is intense leaching (removal of bases, Ca^{2+} (calcium), Mg^{2+} (magnesium), K^+ (potassium), and Na^+ (sodium), and silica as water percolates downwards through the soil profile), which is accompanied by a change in the mineralogy of clay-sized particles, mainly from smectite to kaolinite. Smectite, a 2:1 phyllosilicate mineral, occurs in greater quantity in less weathered-leached soils, which is not the case for Acrisols and Alisols. Along with weathering and leaching processes, smectite tends to break down with changes in soil chemistry, mainly low pH, which releases the elements that comprise part of its crystalline structure. Under these intense leaching conditions, typical of humid subtropical environments, most such bases (Ca^{2+} , Mg^{2+} , K^+ , and Na^+) and silica are removed from soil ecosystems, causing a change in the former conditions that favored the formation of smectite. Thus, other minerals such as kaolinite tend to form ([Kämpf et al., 2012](#)). Moreover, the formation of pedogenetic iron (but not aluminum) oxide minerals is favored under these new soil conditions. Of the main iron oxide minerals in these soils, goethite formation is favored over that of hematite under these climatic conditions, i.e., lower temperatures and greater water content. Humid subtropical conditions also favor the accumulation of larger amounts of

organic compounds, which may complex with iron (Fe) and reduce its availability for the formation of hematite (Schwertmann and Taylor, 1989). In addition, the formation of gibbsite, an aluminum hydroxide also found in very weathered–leached soils, is not favored because in most cases the silica in solution prevents its formation in Acrisols and Alisols (Kämpf et al., 2012).

The humid subtropical environmental conditions under which Acrisols and Alisols form cause mineralogical transformations from easily-weatherable primary minerals (EWPM), e.g., feldspars and micas, to kaolinite mainly in Acrisols (more weathered–leached than Alisols). With these mineralogical transformations, other soil properties are consequently influenced, causing low natural soil fertility (Acrisols and Alisols) and low cation exchange capacity (CEC) (Acrisols). For example, the CEC of smectite tends to be at least 10 times greater than that of kaolinite (Resende et al., 2021), which markedly reduces the negative electrical charges of Acrisols and the capability of their clay particles to adsorb bases and other cations.

In the case of Alisols, the conspicuous presence of hydroxy-interlayered vermiculite (HIV) in the clay fraction is responsible for high CEC values, but these soils still have low natural fertility. This fact indicates that the soil uses and management practices considered for Alisols need to be different from those for Acrisols.

For the ‘organisms’ factor, one may consider both vegetation and fauna present in soils. Together with other factors, they are responsible for the transformation of parent rocks into sediments and, hence, soils, favoring the development of an A horizon. Moreover, while microorganisms are extremely important for the cycling of nutrients by promoting the decomposition of organic residues, vegetation provides organic matter to the soil surface, creates preferential water pathways as the plant roots are decomposed, increases the content of organic matter at depth, and contributes to nutrient cycling by the uptake of nutrients by roots at depth and their eventual incorporation into the plant tissues. Later, these nutrients will be detached from the plant tissues, incorporated into topsoil, and then leached or eroded or taken up again by vegetation. In addition to being a factor of soil formation, vegetation is also influenced by soil properties (together with the climate) that control the type of climax vegetation to be established on it. In areas where Acrisols and Alisols occur under humid subtropical conditions, native forests are common on the various continents. This, together with the lower temperatures of humid subtropical ecozones, favor the accumulation of soil organic matter and its compounds.

Relief may control soil drainage (steep areas tend to have lower water infiltration than flat areas), may enhance erosion, especially on steep slopes with soils deprived of or with little vegetation cover, and resulting in redeposition of sediments, soil organic carbon, nutrients and other elements at lower landscape positions, including floodplains. Therefore, these consequences of relief may increase environmental risks, such as soil degradation through the removal of topsoil and deposition of sediments in water bodies. The predominant relief where Acrisols and Alisols tend to occur is dominantly hilly or undulating, which affects soil depth: moderately deep to deep soils (*solum* thickness ranging from 50 cm to 2 m) but not very deep soils >2 m, which is common with Ferralsols or Oxisols.

Acrisols occur on a great variety of parent materials, mainly from the weathering of acid parent materials such as granite and rhyolite. These rocks have high contents of silica (SiO₂) and are dominated by quartz and feldspars in addition to accessory minerals, e.g., micas and amphiboles. Although Alisols may also develop in different parent materials, they are mainly formed from the weathering of mafic rocks such as basalt, gabbro and diabase, and from unconsolidated sediments. Mafic rocks are Fe- and Mg-rich, mainly composed of Ca- and Na-bearing feldspars (labradorite) in addition to pyroxenes (augite), amphiboles, olivine, and magnetite. Differences in the main parent materials of Acrisols and Alisols tend to promote greater clay contents in Alisols because of the reduced contents of quartz in their original parent material, i.e., mafic rocks. Consequently, Alisols tend to be a less permeable soil system, especially considering that neither Acrisols nor Alisols have a microgranular structure in the B horizon like Ferralsols (Oxisols). In Ferralsols, soil structure is more important than soil texture in terms of physico-hydraulic behavior (Ferreira et al., 1999).

In terms of time, the formation of soils having subsurface argic horizons was estimated to about 29 thousand years (Butler, 1958). This is for general reference only, as it is well-known that rates of soil formation are influenced by multiple factors, such as resistance of bedrock to weathering and climatic conditions, relief (that may promote variable erosion and water infiltration), soil mineralogy, and amount and type of soil organic matter, among others.

Processes of formation of Acrisols and Alisols

The multiple pedogenetic processes that explain soil formation are divided into four main categories: additions, removals, transformations and transfers. Each of these processes affects both the mineral and organic components present in soils, causing differences in soil evolution.

Concerning the formation of Acrisols and Alisols, additions are mainly related to organic matter that accumulates in these soils, mainly but not exclusively in the surface horizons. The B horizons of some Alisols may have larger contents of organic carbon in their upper part. This is probably a consequence of cooler temperatures under which Alisols form and that reduce the rate of organic matter decomposition by microorganisms. Moreover, these cooler temperatures coupled with abundant and well-distributed rainfall during the year favor the formation of dense natural vegetation cover, such as the native forests commonly found in areas with these two soil classes.

Losses are related to the loss of plant nutrients by an intense degree of leaching of these soils, causing low base saturation values and, hence, low natural soil fertility. Other elements (not nutrients) are also leached from these soils. Moreover, the subsurface argic horizon, which reduces water infiltration, makes these soils susceptible to superficial (runoff) losses of mineral material, water,

organic carbon, nutrients and other elements by water erosion, especially on undulating or steeper relief, which is common for both these soil classes. Losses from the interflow of percolation water can also occur, and it may also reach the vadose zone.

Transformations within the profile are mainly caused by the conversion of easily weatherable primary minerals (EWPM), such as feldspars and micas, into kaolinite and other clay-sized particles, such as iron oxides, e.g., goethite, maghemite, and hematite. This is typical for Acrisols. On the other hand, Alisols are characterized by the substantial presence of hydroxy-interlayered vermiculite (HIV) together with kaolinite in the clay fraction.

Transfer reactions can be regarded as the most typical formation process of Acrisols and Alisols. They encompass the translocation of clay minerals from surfacer horizons (A and E horizons) and their accumulation in the argic subsurface horizons (Bt horizon). Consequently, this latter horizon will be enriched with clay compared to the A, E, and C horizons. Clay skins on the surface of peds and pores of this illuvial horizon are common resulting from the deposition and orientation of clay particles eluviated from surface horizons. It is important to mention that some soil fauna (e.g., termites and ants), however, can easily destroy these features in Brazilian Acrisols and Alisols, which is in contrast to the fact that the soil formation processes took millions of years. Moreover, the translocation of clay particles from the surface horizons induces a larger concentration of residual sand-sized particles, causing a texture gradient between the Bt and surface horizons. Translocation results in a series of soil properties that have important effects on both environmental and agricultural issues. Some examples are: reduction in rate of water infiltration and degree of macroporosity (causing some restriction in water percolation); greater difficulty of root growth in the Bt horizon, mainly for perennial crops; and elongated root systems associated with the blocky structure and increase in bulk density, reduced diffusion and consequent uptake of phosphorus, etc. (other consequences are better explained in the following sections). Conversely, the texture gradient of these soils reduces the loss of water by capillary rise because of discontinuity in the soil pores from the Bt horizon (greater clay content and smaller size of pores) in comparison to the greater continuity in pores of the surface horizons (greater sand content and larger pore size).

From the multiple to the specific pedogenetic processes of soil formation, some of the latter considered important for the formation of Acrisols and Alisols are:

- Leucinization: paleness of the lower part of A horizons by the loss or transformation of SOM, producing E horizons (Fig. 3).
- Melanization: darkening of mineral material by mixing with SOM, producing thick A horizons and darkened upper argic subsurface horizons mostly in Alisols (Fig. 4D and F).
- Desilification: release and partial removal of silica from the soil.

Fig. 3 Lessivage, leucinization and ferrolysis (shown in detail in the zoomed portion) with degradation of the top of the Bt horizon in an Acrisol. Source: Prof. Nestor Kämpf's personal archive.

Fig. 4 Variation in soil profiles of Acrisols (A, B and C) and Alisols (D, E and F). Adapted from Streck E, Kämpf N, Dalmolin RSD et al. (eds.) (2018) *Solos do Rio Grande do Sul* (3rd edn). Porto Alegre: UFRGS-EMATER/RS-ASCAR, with permissions granted.

- Brunification, rubefication, ferruginization: release of Fe^{2+} from primary minerals, oxidation and dispersion of Fe oxide minerals, imposing brownish, yellow and red–yellow colors mainly to the matrix of Alisols (Fig. 4D–F), and red colors mainly to the matrix of Acrisols (Fig. 4A–C).
- Argilluviation or lessivage: it is related to the translocation or migration of clay-sized particles from the A and E horizons (eluvial horizons) to the B horizon (illuvial), promoting the formation of a Bt horizon (Fig. 3). Argilluviation is related to the classic vertical migration of clay-sized particles toward Bt horizons (translocation), whereas elutriation or appauvrissement (van Breeman and Buurman, 1998) is caused by lateral movement (multiple process) of clay (and fine silt) particles from the surface horizons by lateral subsurface water flow. This process is facilitated when the impact of water drops previously accumulated on the leaves of native forest trees or direct impact of raindrops on bare soil detach clay particles in a very thin layer of the soil surface, similar to the first step for water erosion. However, instead of being carried away by surface runoff (erosion), these dispersed clay particles are moved from the surface into the first few centimeters of the soil surface horizon. Eventually these dispersed particles can be moved laterally within the soil horizons (i.e., at the contact of the A with the Bt horizon) as subsurface water moves according to the landscape toward lowland areas, including floodplains. In this process, water removes clay-sized particles from the upper horizons, resulting in the accumulation of clay in the Bt horizon.
- Ferrollysis: this process includes reduction, oxidation and hydrolysis. It occurs under seasonal hydromorphic conditions where alternating reduction and oxidation reactions take place during repeated wetting and drying cycles. This reduces the Fe^{3+} present

in phyllosilicate minerals of the surface or upper part of B horizons (much more prone to wetting and drying cycles than the middle and lower part of the B and C horizons). Phyllosilicate minerals are then disintegrated by hydrolysis, which reduces the clay content in the surface and upper B horizons (Fig. 3). This type of pedogenic process explains the presence of the texture gradient between the B and A horizons (Almeida, 1992).

- Xanthization: Yellowing of the surface horizons by SOM complexing with Fe, preventing the precipitation of ferrihydrite and consequent formation of hematite. Therefore, goethite is the dominant form of iron in the upper part of the profile of Acrisols (Fig. 3C), which may result in a bichromic soil profile.
- Erosion: removal of soil material, water, organic carbon, plant nutrients and other elements (not plant nutrients) by water erosion, with (accelerated erosion) or without human interference (geologic or natural erosion). Erosion has varied in importance in features of the Brazilian landscape, mainly in the case of polygenetic soils (Rezende, 1980). In certain regions some Oxisols have been eroded, forming Inceptisols from the material of ancient Oxisols due to the decrease in thickness of the B horizon (Rezende, 1980).

Properties of Acrisols and Alisols

In general, Acrisols and Alisols have some common properties such as the texture gradient related to a greater clay content in the Bt horizon (Fig. 4). However, they also have some important differences. Acrisols, as defined by the World Reference Base for soil resources (IUSS Working Group, 2015), have an argic horizon starting within the first 100 cm from the surface, and a CEC (by 1 M NH_4OAc , pH 7) less than $24 \text{ cmol}_c \text{ kg}^{-1}$ clay in some part of the argic horizon within ≤ 50 cm below its upper limit. These soils also have a base saturation lower than 50% between 50 and 100 cm from the mineral soil surface. Acrisols might also have a hard or cemented or indurated layer in the lower half of the mineral soil above continuous rock, starting below 100 cm from the soil surface. The main adjectives to describe these layers include: Abruptic, Fragic, Leptic, Petroplinthic/Pisoplinthic/Plinthic, Hydragric/Anthraquic/Pretic/Terric, Gleyic, Stagnic, Nudiargic, Lamellic, Albic, Ferric, Rhodic/Chromic/Xanthic, Skeletic, and Haplic. The supplementary adjectives are: Alumatic, Andic, Arenic/Clayic/Loamic/Siltic, Aric, Colluvic, Cutanic, Densic, Differentic, Epieutric, Fractic, Gibbsic, Humic, Magnesic, Nechic, Nitic, Novic, Oxyaquic, Profundic, Ruptic, Sombric, Technic, Toxic, Transportic, Vertic, Vitric (IUSS Working Group, 2015).

Many Acrisols can be correlated with Red–Yellow Podzolic soils (e.g., in Indonesia), Argisols (Brazil) (SiBCS., 2018), Kurosols (Australia), Sols ferralitiques fortement ou moyennement désaturés (France), and Ultisols with low-activity clays (US Soil Taxonomy) (Soil Survey Staff, 2014). Acrisols do not have retic properties, i.e., coarser-textured albic material mixed into a finer-textured argic horizon. Moreover, their name connotes to the Latin word *acer* (very acid), which is a consequence of their relatively strong degree of weathering (IUSS Working Group, 2015, with adaptations).

Alisols also have a base saturation lower than 50% between 50 and 100 cm from the mineral soil surface and an argic horizon, but, conversely to Acrisols, the argic horizon of Alisols starts at a depth greater than 100 cm from the soil surface. They might also have a hard or cemented or indurated layer in the lower half of the mineral soil above continuous rock, starting in the first 100 cm from the mineral soil surface (IUSS Working Group, 2015). The main adjectives of these layers are: Abruptic, Fragic, Leptic, Petroplinthic/Pisoplinthic/Plinthic, Hydragric/Anthraquic/Plaggic/Pretic/Terric, Gleyic Stagnic, Nudiargic, Lamellic, Albic, Ferric, Rhodic/Chromic, Skeletic, and Haplic. The supplementary adjectives are: Alumatic, Andic, Arenic/Clayic/Loamic/Siltic, Aric, Neocambic, Colluvic, Cutanic, Densic, Differentic, Epieutric, Fluvic, Fractic, Gelic, Humic, Hyperallic, Magnesic, Nechic, Nitic, Novic, Oxyaquic, Profundic, Ruptic, Protospodic, Technic, Toxic, Transportic, Turbic, Vertic, and Vitric.

Alisols have high-activity clays (e.g., smectite and vermiculite) throughout the argic horizon. Similar to Acrisols, Alisols do not have retic properties (explained above) by definition.

Many Alisols can be correlated with Parabraunerden (Germany), Argisols (Brazil) (SiBCS., 2018), Ultisols with high-activity clays (US Soil Taxonomy) (Soil Survey Staff, 2014), Kurosols (Australia), and Fersialsols and Sols fersiallitics très lessivés (France) (IUSS Working Group, 2015). Moreover, their name connotes to the Latin *alumen* (aluminum) related to their large exchangeable Al^{3+} content.

Both Acrisols and Alisols may lose Fe oxide minerals, other clay minerals, soil organic matter and other components, resulting in the formation of a bleached E horizon above the argic horizon (IUSS Working Group, 2015) (Fig. 3). As previously mentioned, both soils can also show lateral loss of the clay fraction by elutriation, contributing to the generation or increment of a texture gradient between the Bt and A horizons. This helps to explain the relative increment of the clay fraction in the Bt horizon observed in cases when clay skins do not exist.

The main differences between Acrisols and Alisols are derived from differences in their parent material and degree of weathering (relatively high in Acrisols and moderate in Alisols). Consequently, Acrisols have low-activity clays and Alisols high-activity clays throughout the argic horizon. Their different clay mineralogies increase bulk density and reduce permeability in Alisols (consequence of larger clay content, controlled mainly by the much smaller content of quartz in the mafic parent materials – basalt, gabbro, and diabase) compared with Acrisols (lower clay content, controlled mainly by the much greater content of quartz in the felsic parent materials – granite and rhyolite) (Fig. 5). Table 1 shows the differences in attributes of an Acrisol and an Alisol from southern Brazil.

Fig. 5 X-ray diffractograms of granite and basalt.

Table 1 Examples of differential attributes of an Acrisol and an Alisol from southern Brazil.

Soil	Horizon	Clay content (%)	Exchangeable Al^{3+} ($cmol_c\ kg^{-1}$)	CEC ^a ($cmol_c\ kg^{-1}$)	Al saturation (%)	SOM ^b (%)
Acrisol	A	8	0.45	2.6	17	0.99
	Bt	58	2.15	9.8	22	1.21
Alisol	A	52	1.7	16.2	24	4.06
	Bt	65	5.9	9.3	86	0.36

Data from Acrisol were selected from Almeida (1992) and data from Alisol were selected from Curi (1975).

^aCEC – Cation exchange capacity.

^bSOM – Soil organic matter.

Kaolinite tends to predominate in the clay fraction of both Acrisols and Alisols. However, in the latter HIV is also present in its clay fraction together with a smaller kaolinite content than in Acrisols (Fig. 6). Quartz is present, but gibbsite has not been detected in the X-ray diffractograms of both soils (Figs. 5 and 6), although it can be present in very small amounts only in some samples.

Some explanations for the above features are related to the fact that Alisols tend to occur at higher altitudes than Acrisols, at least in southern Brazil; therefore, Alisols are associated with less weathering than Acrisols because of the lower temperatures at higher altitudes. The mafic parent material of Alisols also has much less quartz content and tends to produce soils with higher clay content than the felsic parent material of Acrisols (Fig. 5). Moreover, this difference in parent materials tend to form Alisols that have greater density and are more impermeable than Acrisols. These differences in parent material help to explain the presence of high-activity clays in the Bt horizon of Alisols and the low-activity clays in the Bt horizon of Acrisols.

Hydroxy-interlayered vermiculite (HIV) is a pedogenic clay mineral with Al-hydroxy interlayers formed in acid environments by the intercalation of Al polymers in the interlayer space of the 2:1 structures of vermiculite (more common) and smectite (less common). The Al-hydroxy polymers modify substantially the physico-chemical properties of these clay minerals. The extent of such alteration is proportional to both the degree to which the interlayers are filled with Al-hydroxy polymers and the stability of these components (Kämpf et al., 2012).

The conditions that favor the formation of interlayer Al-hydroxy laminae in vermiculite and smectite are: active weathering to release Al^{3+} ions; moderately acid environment, around pH 5; low soil organic matter content to prevent Al complexation; and frequent wetting and drying cycles (Rich, 1968). Many authors, for example Barnhisel and Bertsch (1989), have demonstrated experimentally the processes of formation of such clay minerals and changes in the physical and chemical properties of the original vermiculite and smectite.

Hydroxy-interlayered vermiculite tends to occur mainly in the coarse clay fraction (2–0.2 mm) of soils and has increased concentration in the surface horizons of Alisols (Curi et al., 1984), indicating its pedogenic formation and strong resistance to weathering. The HIV is more stable thermodynamically than kaolinite (Karanthanas, 1988). The Si biocycling can also contribute to its stability in the surface horizons of soils (Kämpf et al., 2012).

Fig. 6 X-ray diffractograms of the clay fraction of an Acrisol and Alisol.

In terms of environmental importance, the filling of vermiculite and smectite interlayers by Al—OH (common) and Fe—OH (less common) produces significant changes in the chemical and physical properties of these clay minerals: increase in variable charge, and reduction in internal specific surface area and of swelling–shrinkage capacity. The fixation of anions (phosphates, borates, sulfates) and heavy metals has been attributed to these Al-hydroxy interlayers (Barnhisel and Bertsch, 1989). Moreover, this fixation is the cause of very large exchangeable Al^{3+} content under certain soil environmental conditions (Marques et al., 2002).

Sustainable use and management of Acrisols and Alisols

In humid subtropical conditions, soil and water conservation are crucial for agriculture on Acrisols and Alisols because of the undulating or steeper relief on which they generally occur. Considering low and intermediate technological management systems, they are most suited for use with perennial crops because of the small number of annual interventions. Within this scope, extensive pasture (low technological systems) and forestry (intermediate technological systems) constitute sustainable land uses.

Under advanced technological management systems, including the control of water erosion and soil compaction, liming or the use of agricultural gypsum and fertilizer applications, crop succession/rotation, appropriate genetics and mechanization in all phases of the production process, Acrisols and Alisols can achieve high productivity for maize (*Zea mays* L.), soybeans (*Glycine max* (L.) Merrill, wheat (*Triticum aestivum* (L.), etc., in particular under no-till management systems (Peixoto et al., 2020).

Gradient terracing (prepared with a small degree of unevenness transverse to the greatest slope) is recommended for soil and water conservation, to take account of the decrease in permeability in the Bt horizon of Acrisols and Alisols. The poor natural soil fertility is common for both soil types due to their relatively high (Acrisols) and moderate (Alisols) degrees of weathering, with a need for liming and fertilization. Larger contents of exchangeable Al^{3+} are common in Alisols, which require substantial amounts of lime or gypsum for sustainable cultivation of the most sensitive crops. When Alisols are managed appropriately for soil acidity and are adequately fertilized, the crops can benefit from their high activity clays (high CEC) and adequate water-holding capacity; they behave similarly to Luvisols which have high activity clays and a large base saturation (IUSS Working Group, 2015). Extensive pastures, acid-tolerant crops and forestry (with eucalyptus (*Eucalyptus* L'Hér.) and pines (*Pinus* L.)) are suggested in the adoption of low and intermediate technological systems for soil management and land cultivation.

The nature of HIV clay minerals has resulted in their dynamic transformation by soil management practices (Kämpf et al., 2012). In this context, management systems that favor the accumulation of organic compounds in soil, (for example, no-till) can, in the long term, destabilize and remove this Al-hydroxy interlayer from vermiculite (Inda et al., 2010). This results in an increase in acidification, which needs appropriate amendments based on soil analyses and monitoring.

Fink et al. (2014), based on a 10-year experiment in an Acrisol under humid subtropical conditions, tested the following treatments: native field (NF), crop under a no-till system without the application of poultry litter (NPL), crop under no-till system with the application of poultry litter (PL), and native pasture with the application of manure and cattle droppings (CD). They concluded that the change in land use to CD promoted dissolution of the 2:1 clay minerals (including HIV), which was shown by the decrease in reflection intensity of these minerals and their area in the X-ray diffractograms, and by the greater activity of Al and Si in the soil solution, corroborating the dynamic nature of these clay minerals under different soil management systems.

A comparison of phosphorus (P) adsorption in Acrisols and Alisols with Ferralsols and Nitisols by Oliveira et al. (2020) showed that it was positively correlated with soil clay and organic matter contents, and specific surface area. The clay minerals most strongly influencing P adsorption were goethite, followed by hematite and gibbsite. These clay minerals represent an increasing order of crystal size (Kämpf et al., 2012), and as the Acrisols and Alisols have smaller contents of the Fe oxide minerals than the Ferralsols and Nitisols, their P retention is much smaller. This results in a potential saving of P-fertilizers for sustainable crop production under moderate and high technological management systems.

Conclusion

Acrisols and Alisols in the humid subtropical ecozone occur on different continents, mostly in their southeastern and southern regions. The main differences between Acrisols and Alisols are derived from differences in their parent materials and degree of weathering (greater in Acrisols than in Alisols). However, both soils have an argic horizon in the subsurface, which can increase the risks of water erosion because of delayed infiltration. These processes are exacerbated because of the undulating or steeper relief on which they generally occur. This reinforces the need to adopt sustainable conservation practices, such as gradient terracing, to avoid losses of soil material, water, organic carbon, plant nutrients and other elements (non-nutrient). With proper land use and management systems, both Acrisols and Alisols can be highly productive and sustainable.

Abstract

The tropics are between the equator and Tropics of Cancer and Capricorn. They change with latitude from perhumid to seasonal rainfall. The vegetation period extends to the entire year around the equator down to at least 90 days at higher latitudes. Parent materials and age of the landscapes also differ. They include old strongly weathered landscapes (e.g., Southern India), young river basins (e.g., Amazon Basin) and active volcanic areas (e.g., Indonesia). The older fluvial landscapes are rather levelled, but in tectonically active and volcanic landscapes relief energy can be large. Characteristic zonal soils are Ferralsols in the perhumid and Acrisols in sub-humid climate zones. In addition, depending on parent rock and relief Nitisols, Luvisols, Plinthosols, Andosols and Vertisols also occur.

Key points

- In the humid and sub-humid tropics there is a contrast between old table lands and low lying river soilscapes.
- Lateritic weathering occurs in the tropics, but it is only found in landscapes with long lasting continuous weathering.
- Desilification is a prominent process in acid tropical soils.
- Clay illuviation occurs mainly in landscapes with seasonal climate.
- The “Terra preta” represents an anthropogenic improvement of chemically poor soils.

Introduction: Delineation of tropical soils

The tropics are the area where the sun reaches the zenith position, i.e., an angle position relative to the ground of 90° during at least 1 day of the year. This is exactly to a latitude of 23° 26′ 5″ north and south from the equator at present. At the continental scale climate is the major variable for explaining soil variation, but at higher resolution (i.e., regional) parent material and landscape age (i.e., time for undisturbed soil development) become more important. At the landscape scale, relief is a major explanatory variable.

In total, we find about 10 soil zones around the world (Table 1 and Fig. 1). Three of these occur in the tropics (Mohr et al., 1972), namely the rainforest Ferralsol-Fluvisol-Gleysol zone, the Savannah Nitisol-Acrisol-Vertisol zone, and the semi-desert Regosol-Calciisol-Solonchak zone (FAO, 2015; IUSS, 2022). The latter leads over to the subtropics, is less relevant for land use, and therefore, will not be covered here.

The tropics can be subdivided into three major landscape types: 1. The old remains of the big southern supercontinent Gondwana in Brazil, Central Africa and Southern India, which are tectonically stable and thus have been subject to weathering

Table 1 Soil zones and their characteristics including the tropics with increasing latitude.

<i>Soil zone</i>	<i>Climate (Köppen)</i>	<i>Natural vegetation</i>	<i>Suitability</i>	<i>Soil fertility</i>	<i>Natural productivity</i>	<i>Minimum factors</i>
1. Ferralsol–Fluvisol–Gleysol	Af	Tropical rainforest	Forest, agriculture	Low	High	Nutrients (K, P, N)
2. Acrisol–Nitisol–Plinthosol–Vertisol	Aw	Savanna	Forest, agriculture, pasture	High	Medium-high	Water, nutrients (P, N, K)
3. Arenosol–Leptosol–Gypsisol–Solonchak	Bsh/BWh	Extreme desert	–	Low	Very low	Water
4. Regosol–Calcisol–Solonchak	BS	Semi-desert	Pasture, agriculture	Medium	Low	Water, salt
5. Chromic Lixisol–Acrisol–Calcic Cambisol–Planosol	Csa	(Evergreen) sclerophytic forest	Agriculture	Medium-high	High-very high	Degradation, nutrients (N, P)
6. Kastanozem–Chernozem–Phaeozem–Solonetz	D/BS	Steppe	Pasture, agriculture	Very high	Medium	Water, heat
7. Cambisol–Luvisol–Gleysol	Cfb, (D)	Deciduous forest	Agriculture, pasture	Medium	Medium	Heat, nutrients (N), water
8. Podzol–Retisol–Cambisol–Histosol	Df	Taiga	Forest, (pasture)	Low	Low	Heat, nutrients (N)
9. Gelic Regosol–Cryosol–Gellic Gleysol	ET	Tundra	Pasture	Low	Very low	Heat
10. Ice-covered–Gellic Leptosol	EF	Cold desert	–	Very low	Lacking	Heat, water

Meaning of Köppen abbreviations: Capital letters: A equatorial, B arid, C warm temperate, D boreal, E polar, F polar frost, S steppe, W desert. Lower case letters: a hot summer, b warm summer, f fully humid, h hot arid, s summer dry.

Fig. 1 Map of global soil zone distribution. Adapted from Schultz, J. (1995) *Ökozonen der Erde*, 2nd edn. Ulmer, Stuttgart.

and soil development since the Jurassic period; 2. The large river floodplains of the Amazon and the Congo; 3. The young volcanic regions of Central Africa, Indonesia, the Philippines and South America. Towards the sub-humid and semi-arid areas, there are increasingly younger sedimentary environments (Tertiary to Quaternary in age) that are remnants of climate change in the past.

Factors governing soil development and fertility

The water budget at a site, i.e., the ratio of rainfall to evapotranspiration determines the direction of water movement in the soil and thus the rates of weathering and mineral neoformation. The latter two are modified by the parent material, i.e., fabric, mineral and geo-chemical composition, and these latter components affect the potential nutrient status. The time taken for soil formation determines the rate and state of weathering, and the fertility status. Therefore, soils cannot be understood without considering these three major factors: climate, parent material and time. Relief resulting from tectonic processes, surface erosion and sedimentation also play a role at the landscape scale, and recently human influence has become important. Therefore, these aspects are elucidated in more detail in the following.

Moisture and temperature conditions (climate)

A globally accepted approach to categorize the climate effect on soil has been developed by Soil Survey Staff (1999) on the basis of the Köppen climate classification (1936). It differentiates so-called soil moisture regimes (SMR), and soil temperature regimes (STR).

Soil-moisture regimes (SMRs) are defined to classify a soil's ability to supply water to annual plants and crops without irrigation. In soils where the groundwater table is not reached by the roots of these plants, the SMR is determined by the seasonal distribution of rainfall in "normal" years. Most food crops require a reliable supply of water for at least 90 consecutive days.

The perudic SMR has precipitation that exceeds potential evapotranspiration every month of normal years. Although this may seem desirable, these areas have weed, insect, and disease problems, and the constantly humid conditions make it difficult to harvest mature grain crops.

The udic SMR has fewer than 90 cumulative days when water is not available in the rooting zone in normal years. It is possible to grow food crops any time of the year without irrigation when the temperature is warm enough for the particular crop. Available water is less reliable during some parts of the year, and farmers often select more drought-tolerant crops, but perennial plants are adequately supplied with water throughout most years in the udic SMR areas.

The ustic SMR is borderline to the common concept of humid. In normal years, soils with an ustic SMR have at least 90 consecutive days when moisture is available, but more than 90 cumulative days when water is not available in the rooting zone. Natural vegetation is either seasonal rain forest or savanna. At least one crop can be grown reliably each year, and it is possible to have two harvests per year on some soils, but there is a seasonal dry period of 90 days or more when crop production is not possible without irrigation. The reliable dry season of the ustic SMR is a distinct advantage for weed and disease control and grain-crop harvest in isohyperthermic and isothermic STRs.

Soils that have a reliable moisture supply for fewer than 90 consecutive days in normal years have an aridic SMR and are excluded from the concept of this chapter.

The above SMRs are used to classify only the well-drained upland soils. Groundwater often saturates the rooting zone of some soils within all areas of the tropics. These soils are identified as having an "aquic soil moisture condition."

Mean annual soil temperatures are 2–4 °C warmer than mean annual air temperatures. Soil-temperature regimes (STRs) are defined by two criteria, mean annual soil temperature and seasonal temperature difference. Seasonal soil-temperature difference is determined as the mean soil temperature of June to August compared with the mean soil temperature of December to February. Almost all of the soils within the geographic tropics have soil temperatures that differ seasonally by less than 6 °C and are identified by the prefix "iso" placed before the name of the STR. Except for a few soils near the northern and southern extremes of the geographic tropics in Africa, this characteristic is the only soil property that is almost universal with the concept of tropical soil. The practical aspect of this soil property is that seasonal soil temperatures seldom have to be considered when planting food crops.

Soils with mean annual soil temperatures of 22 °C or higher are classified as isohyperthermic; soils with mean annual soil temperatures of 15–22 °C are identified as isothermic. Freezing conditions are seldom a problem in the isothermic and isohyperthermic STRs except for high mountain areas. Higher elevations in tropical areas have isomesic STRs, with mean annual soil temperatures less than 15 °C; crop growth is slow, night-time freezing is common.

Throughout the areas concerned the temperature is warm or hot all year round. No plants or animals living there need to have any adaption to reduced heat. In the rainforests the air and soil temperature do not change by more than 1 degree centigrade during the year. However, in the savannas during the dry season the temperature in the topsoil may become very hot, and therefore organisms need heat adaption. From both zones, an example of a typical climate has been selected (Figs. 2 and 3). Manaus is a typical case of the humid tropics and has, according to the Köppen–Geiger system, an Af-climate (Köppen, 1936). The average temperature at almost sea level is 26.6 °C and the annual rainfall amounts to 2272 mm. More important, there is no dry season. Consequently, there is a good water supply all year round. For the other case, Brasilia is taken as the example. Here at an altitude of 1158 m a.s.l. the average temperature is 20.7 °C with 1555 mm annual rainfall. This is classified as an Aw-climate. Because of the dry season the growing season is restricted to around 9 months. In other areas in the savanna the dry season may be up to 6 months, and the temperature may rise above 30 °C. There is a need for organisms to adapt to drought and heat.

Fig. 3 Climate diagram for Brasilia, the capital of Brazil, situated in a typical savanna region. Example for an udic soil moisture and isohyperthermic soil temperature regime. Aw represents the climate classification: equatorial, “dry winter.”

Old continents and young landscapes (time and parent material)

Soil landscapes in the humid and sub-humid tropics have developed under two extremely different geological and geomorphological situations. The Amazon and Congo basin as well as the Indonesian Archipelago are very young landscapes under strong fluvial or volcanic influence. The others such as Southeast Brazil, West Africa, India and Western Australia are old consolidated continents where soils developed from Palaeozoic or Precambrian sediments, as well as metamorphic and plutonic rocks. Even in young landscapes, deep solum development through podsolization in sandy substrates or peat formation in endorheic depressions is possible. Nevertheless, weathering of the solum and solute transport may reach 50-m depth on the old continental landscapes, leading to the deepest weathering transformations in the world. It is important to realize that most of these soils formed under a tropical climate, but equally important is that they are very old weathering remnants. They may date back to the Jurassic period. During these long periods, continental movement plays a role and variation in climate over time needs to be considered. For example, one can find what is perceived as the results of “tropical” weathering, i.e., plinthite and bauxite in the nowadays non-tropical southwest Australia (Kew et al., 2008).

Lowlands, uplands and mountain ranges (relief)

Tropical landscapes can be roughly divided into three major units. First, the old remains of the big southern super-continent Gondwana in Brazil, Western and Central Africa and Southern India. These generally form levelled upland areas. They are strong and deeply weathered, and often also large in spatial extent. Second, the large river systems, for example of the Amazon, Congo as well as Niger can form huge floodplains, inland deltas, and lowlands ending in peri-marine marshes. These latter ones provide the opposite situation: young landscapes and soils with current weathering. These soils are generally in equilibrium with the actual environmental conditions. Finally, there are younger undulating landscapes mostly generated by younger volcanism such as in the Americas, Central and Eastern Africa and building up Indonesia and entirely forming the Philippines. Here soil formation may start on newly solidified lava, but may have occurred over a much longer time. These three units provide totally different weathering environments, since they differ with respect to age, parent material properties, topography and water residence times. Therefore, these three completely different landscapes dominate the different soilscapes.

Biotic diversity and interrelation with soils (termites and their multiple roles)

While earthworms (Lumbricidae) and ants (Formicidae) are more important soil organisms in the sub-tropics and temperate climates, termites (Isoptera) appear to be the more relevant soil animals in tropical soils due to their structural diversity. While earthworms reach dominance in specific landscapes (e.g., wet lowlands with sufficiently high pH-conditions), termites appear in all types of environments and even within the vegetation cover.

Termites are so widespread since they have a wide range of feeding behavior. When living in symbiosis with different microorganisms, they are able to digest totally stable organic material such as lignin and cellulose (Vargo and Husseneder, 2009). More than 2900 species have been identified (Parman and Vargo, 2008) and their sizes range from 2 to 20 mm. They mostly live in state-like organizations with up to 3 million individuals, and build nests and mounds that greatly influence physical, chemical and biological soil properties. By preferentially transporting particles and aggregates of specific sizes in horizontal as well as vertical directions, they contribute to bioturbation, sorting and other soil formation processes. This cannot be underestimated in relation to soil development because of their activity rates over long time periods.

Fig. 4 Termites cover litter with soil aggregates to prepare it for consumption, hidden from predators. Surface of an Acrisol near Bhubaneswar (India) Photograph by Stahr.

An obvious effect of *Macrotermes* species, for example, is to cover dead plants with soil material (Fig. 4). Together with the plants they are protected from predators, and plant material can be transported later to their mounds for further digestion and consumption. Roughly, we can estimate that the belowground volume of a termite mound as depicted in Fig. 5 is at least as big as the aboveground volume. Termite mounds are nutrient accumulation sites since plant material is actively incorporated. The changes in soil properties and structure can still be detected decades after the mounds have been abandoned.

In particular, aboveground as well as belowground mound building termites change the soil hydrological properties. Apart from the mound itself, termites can build galleries that reach down to where water can be collected, i.e., several meters, and they can construct larger hollows for intermittent storage (Fig. 6). All these aspects underline the importance of soil organisms for tropical soil morphology, genesis and properties.

Lateritic weathering as central concept for the tropical soil and landscape development?

Laterite is derived from the Latin word for “later,” which means brick. The term was first used by Francis Buchanan in 1807 (cited in Aleva, 1994) when he described field observations in Madras: “*the most proper English name would be Laterite, from lateritis, the appellation, which may be given to it in science.*” Laterite, with the meaning of a hard outcrop (often seen as rock), is often observed in the tropics at the surface due to erosion. It is perceived as a product of intensive long-term weathering of diverse parent rocks.

Fig. 5 Termite mound incorporating a living tree. Mound surrounded by silt material eroded from the mound (Central Somalia; Luvisol). Photograph by Stahr.

Fig. 6 Acrisol with termite caves in the E-Horizon (Bhubaneswar, India) Photograph by Stahr.

Under these conditions most minerals weather and some more easily soluble elements are depleted such as sodium (Na), potassium (K), calcium (Ca), magnesium (Mg) and silicon (Si). This often results in a residual accumulation of iron (Fe) and aluminum (Al), which is known as ferralitization. Hereby residual quartz and new formations of kaolinite, goethite, hematite, maghemite, gibbsite and other pedogenic Al-oxides can be enriched (Aleva, 1994).

There is a wide range of observations, which have been called laterite (Aleva, 1994). Among these have been rocks, land surfaces and soils. As a result, the definition of laterite became too ambiguous. Consequently, the terms “laterite” and “latosol” disappeared in modern soil systematic considerations and have been replaced by more specific ones.

A typical sequence of horizons has been described in different continents such as Asia (India), Africa (Nigeria) and America (Brazil) (compare Figs. 7 and 8). The complete sequence starts with a Haplic Ferralsol (according to the World Reference Base for Soil Resources, FAO, 2015), or Oxisol (Buol and Eswaran, 2000). This upper part of the sequence is often disturbed by erosion, translocation and sedimentation. The second part is enriched in iron and residual aluminum. It often hardens irreversibly upon drying, and is then called plinthite (“ironstone” Figs. 7 to 9).

In the plinthite and in the following mottled horizon (Fig. 8c) residual biostructures are often observed. The mottled horizon has pale and red parts, which are evenly distributed. The iron content is much lower than that of the horizon above. Below the mottled horizon, there is a bleached zone (Figs. 7 and 8a). Here iron is merely absent and there are residual aluminum compounds and quartz. The enrichment of aluminum may be sufficiently strong that it can be used as an ore. It is then known as bauxite, namely derived from the occurrence and former mining at Les Beaux-de-Provence in southern France (Valeton, 1972; Fig. 9). Saprolite follows further down the profile. This is the first zone, where the structure of the parent rock is preserved, but the material becomes soft. Silicates, however, show isovolumetric weathering and can often be totally transformed into kaolinite. Sometimes underneath this layer there is an abrupt boundary at which the unweathered parent rock appears. Each of the zones described has a thickness of several meters, and therefore the sequence has a total thickness of 10–50 m.

Fig. 9 Vertical distribution of elements and minerals in a lateritic weathering profile in southern India. Modified after Valeton I (1972) *Bauxites*. Amsterdam: Elsevier.

Leaching of bases and desilification are prominent soil forming processes that are observed throughout. The rates of residual accumulation depend on the different weathering zones.

With respect to residual minerals, they concentrate abundantly like quartz and others such as anatase, titanite, ilmenite, staurolite, tourmaline, and zircon. Further, more typical neoformed minerals are present: kaolinite dominates, and in addition gibbsite, goethite, hematite, maghemite and also secondary quartz occur (compare Fig. 9). In particular, Si, Fe, and Al show distinct depth trends. While Fe and Si are completely lost in the bleached zone, Al is residually enriched. Silica is lost by lateral transport from the landscape. Some of the iron can accumulate in the upper parts of the soil profile (plinthite, mottled zone). Together with

the iron, some “heavy” elements may be enriched, either because they are also redox sensitive or because they are incorporated into minerals that hardly weather and enrich residually.

Iron minerals such as goethite, hematite and maghemite are all neoformed. Through relative and absolute enrichment two types of ores are formed (Schellmann, 1994). In the plinthite zone we can find lateritic or plinthitic iron ores (Figs. 8a–c and 9), while in the bleached zone bauxitic aluminum ores (Figs. 8a and 9) often occur.

The frequent occurrence of lateritic weathering profiles under different environmental conditions has led to different hypotheses about their formation. The most important ones are presented in the following:

- (1) The one that is probably the most supported is the residual accumulation hypothesis: This is based on the idea that due to permanent hydrolytic weathering and leaching an absolute loss of mainly K, Na, Mg, Ca, and Si occurs. The result is a residual enrichment of elements and stable minerals, i.e., Al and Fe in oxides, Ti (titanium) in rutile, and Zr (zirconium) in zircon. This approach leaves the complex horizonation unexplained as well as the differences in the Fe to Al ratio.
- (2) The second one is the groundwater hypothesis: During long periods iron was transported downslope into depressions and became enriched in soils where the groundwater table fluctuated (Bl horizon). Below this the groundwater is permanently present (Br horizon) and leads to a reduced bleached zone. The laterally moving groundwater exports elements out of the landscape. Later after (relative) uplift of the landscape long lasting erosion processes led to subsidence of the surrounding landscape and incision by the rivers. In this way, the iron-enriched plinthite became aerated and transformed into petroplinthite. This process conserved the former Bl horizons. The continuous lateral erosion finally resulted in an inversion of the relief, i.e., the former lowlands now form the plateaux.
- (3) According to the Stagnosol–Gleysol hypothesis, three phases occur. In the first phase mottles and or concretions are formed due to water stagnation. In a second phase, alternating groundwater levels occur that increase over time and depth, and lead to deep soil development and enrichment of iron in the concretionary horizon. Finally, the groundwater table continues to lower.
- (4) Following the slope gley hypothesis, in the central part of a plateau water stagnation occurs. There, iron is mobilized and transported laterally to the fringes. There it becomes oxidized and is precipitated. The typical element distribution, as shown in Fig. 9, cannot be totally explained by this process description.
- (5) The floating ore hypothesis is based on the observation that in some plinthites rock fragments have been observed. Understanding of the process is as follows: first phase, ferrallitic soil development results in a relative enrichment of Fe and Al; second phase, the ferrallitic material is eroded and transported along the slope. It is deposited down the slope and then cemented. In fact, in many landscapes of western Africa several laterite generations at different elevations can be observed within one landscape, supporting this hypothesis. However, the original occurrence at the highest landscape position cannot be explained in such a way.
- (6) Finally, we have the karst hypothesis. This relates to the fact that plinthite can be observed in limestone areas (e.g., at Les Beaux-de-Provence, southern France). The concept is that decalcified material accumulated in large karstic hollows. Then, following desilification leads to the enrichment of Fe and Al. Understanding of this process more or less follows the residual accumulation hypothesis, but related to a specific parent material only.

In conclusion, lateritic weathering profiles cannot be explained fully by one of the above hypotheses alone. A combination of the first two is the most probable; it is supported by the data and appears reasonable given the long time spans necessary for the genesis of laterite during which climate fluctuations definitely occurred.

Soils, processes and landscapes

Humid zone river soils (Fluvisol, Gleysol, Histosol, Podzol, Terra preta; India, Congo, Brazil)

Note: In the following we use the World Reference Base for Soil Resources (FAO, 2015) terminology in the text. Where useful, Soil Taxonomy (Soil Survey Staff, 1999) terms are given in brackets.

The major river basins in the tropics include the Amazon, Orinoco, and Paraguay river basins in South America, and the Congo basin in Africa (Monger, 2005). The basins are composed of sedimentary materials derived from surrounding uplands and mountains. The western part of the Amazon basin and the central part of the Congo basin have udic and perudic SMRs and an Af-climate, while the eastern portion of the Amazon basin grades into an ustic SMR. Ferralsols (Oxisols) predominate in the Congo and eastern Amazon basin. The sediments of the latter derive from the Guyana and Brazilian shields.

Fluvisols and Gleysols are widespread in the lowlands (Fig. 10). In particular, settlements are traditionally found on Fluvisols, because drinking water occurs close to the surface, and the rivers provide transport arteries and offer protein-rich food, i.e., fish. Sustainable horticulture and fruit cultivation can be practiced here because water in the root zone rarely runs short, and the steady water flow delivers nutrients. Gleysols and Histosols are less favorable for arable farming, except for crops such as paddy rice (*Oryza sativa* L.) and sugar cane (*Saccharum officinarum* L.) that grow well in marshy areas.

Nitisols and Acrisols (Ultisols) predominate in the western part of the Amazon basin, where the sediments derive from the Andes and are consequently slightly more nutrient-rich than those towards the east. Both Acrisols and Ferralsols are by definition nutrient-poor soils. However, local inclusions of more nutrient-rich parent materials are present. Luvisols and Eutric Nitisols (Alfisols) have formed in these more base-rich sediments of western Brazil and on the eastern borders of the Congo basin. Many areas with these more fertile soils in the chemical sense, are being cleared of forest for crop production and cattle grazing.

Fig. 10 Cross section through a floodplain at Rio Babahoyo in the lowlands of Western Ecuador. Graph by Stahr and Herrmann.

Some of the sediments in the basins are sandy. Where the water table occurs at depth, soils formed from such sediments are chemically infertile Arenosols (Quartzipsamments) or (giant) Podzols (Spodosols). It has been estimated (Klinge, 2006) that about 10% of the Amazon basin is covered by these kinds of soils, e.g., in the headwaters of the Rio Negro in the northwestern Amazon basin, where it merges with the Orinoco watershed. Histosols and Gleysols are also widespread there. Smaller areas of these sandy soils are scattered throughout the basins, often detectable by coffee-colored “black” waters of the rivers that drain these watersheds. So-called white sands ecosystems have recently captured more interest in the marshy areas (Klinge, 2006; Bleackley and Khan, 1963; Atwell et al., 2023).

The Terra preta story

Many tropical soils are considered to be degraded, though the definition of what degradation in this context means is seldom defined. In particular, in subsistence-oriented farming systems, fertilizer input amounts are small and fallow times are decreasing. This eventually leads to a decrease in soil organic matter and plant available nutrient concentrations.

To increase soil fertility, much attention has been paid to what is called “Terra preta.” These anthropogenic soils (WinklerPrins, 2014) were first discovered in South America; they have a deep topsoil enriched in organic matter with a greater share of so-called black carbon. The latter is an organic matter fraction that is rather resistant to microbial decay (Glaser and Woods, 2004). The Terra preta (Pretic Anthrosol) concept has much in common with the Hortisols or Plaggenesch (Hortic or Plaggic Anthrosols) in northern Germany and the Netherlands.

The major question is whether Terra preta is, in general, a suitable concept to increase the chemical fertility status of tropical mineral soils. To answer this question one has first to acknowledge that Terra preta are sites of accumulation; they cannot develop from the biomass production at the sites themselves, but depend on the input of organic matter from other sites. This means that in areas with a high population density, and where all surfaces are already under agricultural use, sufficient biomass as a source of input is rarely available. This is particularly true for the Sahelian Arenosol belt south of the Sahara desert.

Where sufficient external biomass is available, the question arises as to whether it would be better to use the biomass for soil C and thus nutrient cycling rather than increasing the C-stock. Increasing the C-stock makes particularly good sense in soils with low cation exchange capacity, e.g., Arenosols. But as described above, in the areas where the latter are prominent, the external biomass available is insufficient to build up Terra preta. And if one looks at the rates of application in scientific publications, the inputs are far from what is manageable in a subsistence context (compare also Feil et al., 1995).

An additional problem is the effort required to transform biomass, into compost or Bokashi, (inoculated fermented compost), for example, or the application of pyrolysis. The latter needs additional technology that is costly and may lead to byproducts that are potentially harmful, depending on the process management.

In conclusion, application of the Terra preta concept will, in the long run, be restricted to small areas where topsoil cation exchange capacity and organic matter content are low, where sufficient biomass waste products are available from other sources, and sufficient labor is available under the condition of low alternative income possibilities (“opportunity costs”).

Chap. 8.4 Soil Zones of the World. Springer-Verlag Berlin Heidelberg.

Humid tropical uplands (Ferralsol, Plinthosol, Planosol; Brazil, Benin, Thailand)

The remains of the old continents are dominated by deeply weathered ferralitic laterite profiles (Figs. 7 and 8a). The river systems generally cut into the saprolite or even into the unweathered rock. They also have udic and perudic SMRs and an Af-climate and grade at their outside into ustic SMRs, and the influence of groundwater is reduced in comparison to river soilscares above. The plateaux are covered with strongly and deeply weathered Ferralsols (Fig. 11). At the beginning of the slopes they can change to Acrisols or Plinthosols. The latter often form from the hardened plinthite, a morphologically visible step. Beneath the ferralitic material can be found again. In contrast to the Rhodic Ferralsols on top of the weathering sequence these often show xanthic (yellow or golden) color patterns or geric properties. Gleysols occur where streams flow in narrow floodplains. Ferralic Arenosols or even Podzols occur where the parent material is Palaeozoic sandstone (Blume et al., 2016).

Landscapes derived from “acid igneous rock” occur more extensively in Southeast Asia, parts of the eastern highlands in South America, West Africa, the central highlands of East Africa, and eastern India. In these progressively weathered areas, there are Ferralsols on hilltops and in plateau positions, together with Planosols in micro-topographic depressions. Plinthosols with partly petro-plinthic horizons occur on slopes and in slightly eroded places. These topographic positions indicate the influence of lateral transport processes as well as erosion that trigger hardening of the plinthite.

All the soils mentioned above are difficult to use for agriculture because of their poor nutrient status resulting from the intense weathering and leaching. In places, where landscapes were less stable, and consequently soil formation is younger or results from finer-grained basement rocks Acrisols and Dystric Cambisols are prominent, which have a moderate fertility status, but are still commonly deficient in phosphorus (P) and calcium (Ca). In most areas there are inclusions of more base-rich sedimentary rock where Luvisols have formed. In former times agriculture in these areas was limited to slash and burn unless the infrastructure for markets and fertilizers existed (Monger, 2005).

Under certain conditions, however, nutrient status can be high (Singh et al., 1995). On the Deccan plateau of western India, for example, chemically fertile Vertisols have formed on volcanic, i.e., basaltic rocks (Bronger, 2007). The Andean chain along the west coast of South America was formed by tectonic uplift and associated volcanic activity. Some of the uplifted materials are limestones, rich in calcium, while others are granite and schist, relatively poor in calcium but rich in potassium. Tectonic instability, steep slopes, and glaciers at the highest elevations have resulted in rapid erosion of surface materials and deposits of relatively fertile sediments in intermountain valleys where fertile Eutric Cambisols, Regosols and Leptosols occur, but are partly limited by water availability.

Seasonal river soilscares (Fluvisol, Cambisol, Vertisol, Gleyic Solonchak; Amazon, Congo, Niger)

Soils formed in river floodplain sediments and deltas are often fertile (Monger, 2005) either due to their mineral and geochemical composition or they obtain nutrients that are delivered steadily by the flowing groundwater. In the first case, fertility is derived from eroded (top)soil of the surrounding uplands. Consequently, where the soil is relatively rich in essential elements, people can grow and harvest food with little or no attention to the addition of mineral fertilizer. Crop yields are low to medium inter alia depending on the depth to the groundwater, but they are reliable. The soil moisture regime is still udic, the climate, however, is Aw and can have dry periods. Most soils formed on floodplains are Fluvisols, when flooding is still frequent, or Cambisols in more elevated positions. Clay rich sediments are the parent material of widespread Vertisols (Hole, 1961). In addition, Gleysols occur where groundwater appears at a shallow depth. Despite the physical dangers from flooding, human settlements are concentrated in these areas, attracted by the relatively elevated soil fertility, access to water, transport, and protein sources, i.e., fish. Subsistence agriculture

is often practiced, unless flood hazards and groundwater table can be controlled. Narrow areas of floodplains are also present along coastlines throughout the humid tropics with similar types of soil occurring. In the Amazon floodplains long-term used soil and the organic matter-enriched Terra preta occur around traditional villages (see Terra preta section above). They are Anthrosols that have seen intended long-term accumulation of organic inputs.

Sub-humid tropical uplands (Acrisol, Luvisol, Nitisol, Cambisol, Planosol; Benin, Niger, Ghana)

The sub-humid seasonal tropics exhibit a broad range of different soils depending on rock type, relief and particularly the age of the stable land surface (Blume et al., 2016). Strongly weathered and kaolinite-rich Ferric Acrisols and Lixisols occur on the older land surfaces in West Africa (Fritz, 1996), Eastern Brazil and Northern Borneo. Plinthosols are also present there. Younger landscapes with more active morphodynamics (SE Asia), and landscapes with longer dry periods are covered with Nitisols and Ferric Planosols, whereas depressions have gleyic and stagnic variants. In these areas the moisture regime is generally ustic and temperature regime is hyperthermic. The Köppen climate is Aw bordering on the dry side to BS.

Vertisols dominate in areas derived from clay or mudstone with strongly alternating wetting and drying cycles, i.e., pronounced seasonality (Thakur et al., 1999). Consequently, Vertisols can occur at the drier end of the seasonal climates, i.e., in semi-arid landscapes, e.g., in Venezuela and India, and Ethiopia (Bronger, 2007, Murthy et al., 1982). Parent materials with lower clay contents lead to the formation of Lixisols in drier climates, and Nitisols in more humid climates (Fig. 12). Under terrestrial conditions Vertic Cambisols and Chromic Luvisols occur, and on relatively old surfaces Plinthosols are widespread. In Asia, the coastal regions especially are characterized by Gleysols and Fluvisols that have been modified by long-term rice cultivation (Anthrosols).

Plinthosols and Acrisols have very poor nutrient stocks and are therefore often under shifting cultivation in South America and West Africa (e.g., Igue, 2000). Alternatively, they can be used for Al-tolerant perennial crops such as tea (*Camellia sinensis* (L.) Kuntze), rubber (*Hevea brasiliensis* (A.Juss.) Muell. Arg.) or oil palm (*Elaeis guineensis* Jacq.). In contrast, Lixisols and particularly Nitisols can be highly productive if adapted nutrient management is practiced (Bronger and Bruhn, 1989).

Water erosion is a general problem associated with arable farming and particularly in seasonal climates where high rain intensities occur. Despite poor workability, either too dry or too wet, Vertisols are in general nutrient rich (Blockhuis, 1993) due to their high cation exchange capacity and their frequent clay–humus complexes. As fertile sites, they are traditionally used for agriculture, if not too wet for prolonged periods. In drier areas additional irrigation can be favorable, otherwise they also provide good pasture sites.

Young volcanic territories (Leptosol, Regosol, Andosol, Phaeozem; Ecuador, Ethiopia, Indonesia)

A small proportion of the soils in humid tropical areas are formed in relatively nutrient-rich material derived from volcanic activity. A typical representative of weathering from volcanic ash and basaltic materials of various ages are Andosols (Andisols). In a chronosequence, Tephric Regosols are precursors, and Luvisols or Acrisols follow Andosols. Historically, these soils have supported large human settlements. Java, southern Sumatra, parts of the Philippines and other Pacific islands, Central America, the Andean mountains in South America and the Rift Valley in Africa are major areas with volcanic material. Many of these volcanic areas are mountainous and the higher elevations are characterized by isothermic or isomesic STRs where crop performance is reliable, but cool temperatures can slow down crop growth at higher elevations. The volcanic ash regions are naturally the most fertile (Fig. 13). Ash compounds weather easily and therefore deliver nutrients in large amounts to the developing soil. In addition, these soils have low bulk density and therefore good rooting capabilities, and their structure is quite stable enabling high rates of water infiltration. The converse is phosphorus fixation, and in the case of relatively mono-mineral composition there are specific nutrient deficiencies.

Human influences on soil fertility

The predominant soil limitation in humid tropical regions is low chemical fertility (Monger, 2005). Major soils are formed from parent materials that contain very limited quantities of essential nutrients such as phosphorus, potassium, calcium, or magnesium. The most infertile soils are the uplands in the interiors of Africa and South America. Most of these soils are physically deep and have reliable moisture for one or two harvests per year. The most infertile ones do not even support enough natural

biomass to sustain slash-and-burn agriculture. However, where reliable infrastructure has been developed, sustained commercial agriculture can now be practiced. Reliable markets, fertilizer, lime, and fuel supplies are essential. A sufficient amount of phosphorus must be applied and mixed into the topsoil to saturate the iron and aluminum oxide anion exchanger sites to an extent that sufficient phosphorus can be made available for the crops. Coarse-grained carbonates or gypsum need to be applied to raise pH and or inactivate the extractable aluminum. Nitrogen fertilizer is always required for non-legume crops. Potassium becomes a limiting factor if high yields are envisaged. Micronutrients such as copper, zinc, boron, and molybdenum are needed in certain places and for specific crops. After an initial investment is made to alter the less favorable chemical conditions, annual fertilizer requirements are greater than in other grain-growing areas around the world. Modern soil-testing technology should be applied to avoid blanket recommendations for fertilizer application rates.

Somewhat less infertile soils with dense forest vegetation can be and are being used for slash-and-burn subsistence agriculture. The rate at which essential nutrients are released from the minerals is too slow to replenish those removed in rapidly growing food crops. The slow-growing forest vegetation that regenerates in abandoned fields can accumulate enough nutrients in its biomass that—when cut and burned—one or two seasonal food crops can be grown, but only every 10–30 years. These soils have the potential for more intense food crop production if chemically fertilized, which is seldom possible without a market infrastructure.

Human populations in the humid tropics are concentrated on soils formed from materials relatively rich in phosphorus, calcium, magnesium, and potassium. Such soils are primarily located in floodplains and deltas, in areas of volcanic activity, and in upland areas underlain by limestone, base-rich igneous, and metamorphic rocks.

Importing essential elements to compensate for those exported with human food can increase crop yields from all soils. Applying animal and human wastes wherein the essential elements have been gathered from sites distant from the food-growing area is a partial solution in many cultures. However, the concentration of essential elements in organic residue and waste materials is small, transport is difficult, and the rate at which the residues decompose to release inorganic ions for crop uptake is often too low. The most efficient fertilizer strategy is the one that combines organic and mineral fertilization.

Outlook and research questions

We have to differentiate between the two great topics of soil genesis and adapted soil use. With respect to soil genesis and the distribution of soils the large divisions are clear, but detailed processes and their rates are still vague. In particular, the processes of desilification and plinthite formation are still poorly understood and require more attention.

In the humid tropics, the typical conditions provide a growing period and ongoing soil formation that lasts the whole year. Both are reduced in the subhumid tropics of the savanna zone, but there is still a long growing period and strong soil formation, which may have lasted for millions of years. The dynamics of soil formation do not cease because of the consistently high temperatures throughout the year. One of the key processes is the loss of silica. In general, silica is removed from the landscapes and is found in the oceans. On the other hand desilification is a process that needs to be described better in young and old landscapes.

Young soils such as Regosols mostly occur on young or strongly eroded land surfaces. On the other hand, there are old soils, which seem to have a typical tropical history like Ferralsols. There are also specific types of soils that might be not related to the actual processes and relief situation. They often occur in landscapes that have undergone lateritic transformation like Plinthosols, deep Ferralsols and even Cambisols formed from deep and old weathered saprolites in one landscape. To explain such occurrences we have to search for further explanations in the future.

Nutrient recycling and replenishment are crucial for the agricultural use of tropical soils. In many cases, increasing organic matter stock is seen as the solution. However, the question remains as to where these materials can be resourced. In most cases the biomass produced has many different uses, particularly for subsistence farmers, so they are unwilling to leave them on the field. Therefore first, biomass production needs to be increased, which is hardly imaginable without primary mineral fertilizer input. Second, the efficiency of nutrients in the system needs to be increased. Here, placing rather than broadcasting of fertilizer is a solution, in particular for crops with a larger sowing distance. New fertilizer resources need to be exploited, including human urine and feces to increase the rate of recycling and sustainable land use. And finally, the nutrients transported to the cities from agricultural products need to be returned to the farms.

Abstract

Sodic soils are of major concern, especially in semi-arid and arid regions. Soil sodicity results from both natural and anthropogenic processes. Many studies have focused on the adverse effects, that sodic soils have on soil degradation, soil productivity, and associated harmful effects on the agricultural and natural environments. Here, basic processes related to soil sodicity are presented, and their impact on soil physical and hydraulic properties and productivity is discussed. The chapter also presents key insights regarding common practices used to cope with soil sodicity and the reclamation of sodic soils.

Key points

- Soil sodification is a major cause of soil degradation, especially in semi-arid and arid regions.
- Soil sodicity results from both natural and anthropogenic processes.
- Clay swelling and dispersion are the main mechanisms that control sodic behavior in soils.
- The magnitude of sodic behavior depends closely on the electrolyte concentration of the soil solution.
- Sodic soils exhibit poor soil structure and hydraulic properties.

Introduction

The presence of sodium (Na) as an adsorbed cation on the soil exchange phase is found in many soils worldwide. Sodium-affected soils exhibit poor soil water and air ratios which adversely affect water movement in the soil, root growth and plant production, and make the soil difficult to farm when either dry or wet. Consequently, in many cases, such soils have had to be abandoned.

Sodium-affected soils have been referred to in the past as alkali soils. This may have originated from the traditional separation of sodium-affected soils into two groups (Szabolcs, 1979): (1) saline soils (soils affected by neutral Na salts, mainly NaCl (sodium chloride) and Na₂SO₄ (sodium sulfate)); and (2) alkali soils (soils affected by Na salts capable of alkaline hydrolysis, including NaHCO₃ (sodium bicarbonate), Na₂CO₃ (sodium carbonate) and Na₂SiO₃ (sodium silicate)). However, at present, Na-affected soils are referred to as sodic soils, with the realization that Na concentration in the soil solution and its amount on the exchange complex, in conjunction with the total electrolyte concentration, determines whether or not a given soil is sodic, and not the type of the salt.

Problems associated with sodic soils are expected to increase. That is because of the need to provide food to an ever expanding population coupled with the increasing demand for good quality water for the urban and industrial sectors, result in both poorer quality water (e.g., Na-rich treated effluents or saline water) and soils being used for food production. Understanding the behavior of sodic soils and its effects on agriculture and adjacent ecosystems is, therefore, essential to manage sodic soils properly to secure crop production and maintain sustainable agriculture, worldwide.

Definitions of sodic soils

Prior to defining sodic soils it is necessary to present two important properties by which sodicity is evaluated. The first is the exchangeable sodium percentage (ESP) which describes the fraction of adsorbed Na from the cation exchange capacity (CEC) of the soil, and is defined as:

$$\text{ESP} = (\text{Exchangeable Na} / \text{Cation exchange capacity}) \cdot 100 \quad (1)$$

where the CEC is normally determined at a reference pH (7.0 or 8.2). However, instead of CEC it is also possible to use the sum of exchangeable cations (Ca + Mg + Na + K). The second property is the sodium adsorption ratio (SAR) that indicates the sodicity level of the irrigation water or soil solution, and is defined as:

$$\text{SAR} = (\text{Na}) / ((\text{Ca} + \text{Mg}) / 2)^{0.5} \quad (2)$$

where () indicates cation concentration in mmol_c L⁻¹. Thus, SAR has units of (mmol_c L⁻¹)^{0.5}. A more accurate calculation of the SAR is obtained when cation activities are used rather than cation concentrations. Based on soil chemistry considerations, Sposito and Mattigod (1977) in Levy (2012) introduced corrections for cation concentrations due to ion pairs or complexes and arrived at the following empirical relation between true (SAR_t) and measured (SAR_p) SARs:

$$\text{SAR}_t = 0.08 + 1.15\text{SAR}_p \quad (3)$$

In arid and semiarid soils, irrigation may lead to dissolution or precipitation of CaCO₃, depending on soil pH and the CO₂ partial pressure (pCO₂) of the system. Thus, the SAR of irrigation water (SAR_{iw}) may differ from that of the drainage water (SAR_{dw}), with the latter being considered a better indicator for sodicity hazard. It has been further suggested that SAR_{dw} be calculated based on the concentration of Na and Mg in the irrigation water, leaching fraction, and Ca concentration in equilibrium with CaCO₃ at a given pCO₂. However, for soils containing gypsum (CaSO₄), Callaghan et al. (2016) proposed the use of equilibrium geochemical modeling for adjusting SAR of saturated paste for gypsum dissolution.

Recently, Rengasamy and Marchuk (2011) proposed an alternative index for water quality instead of SAR, namely the cation ratio for soil structural stability (CROSS) index. The CROSS index considers the effects of all four major cations present in the irrigation water:

$$\text{CROSS} = (\text{Na} + 0.56\text{K}) / (\text{Ca} + 0.6\text{Mg})^{0.5} \quad (4)$$

where all cation concentrations are expressed in mmol L⁻¹. Further generalization of the CROSS index based on both clay dispersing and flocculating abilities have also been proposed.

Exchange reactions take place between the soil solution and the exchangeable phase. Thus, soil ESP can be estimated from the SAR of saturated paste extracts using the following empirical relationship (USSL Staff, 1954):

$$\text{ESP} = 100(-0.0126 + 0.01475 \cdot \text{SAR}) / (1 + [-0.0126 + 0.01475 \cdot \text{SAR}]) \quad (5)$$

or from the monograph presented in USSL Staff (1954). When more dilute extracts are used, such as 1:5 soil:water ratio, then a different relationship holds (Rengasamy et al., 1984):

$$\text{ESP} = 1.95\text{SAR} + 1.8 \quad (6)$$

Fig. 1 Threshold values of sodium adsorption ratio (SAR) and electrical conductivity (EC) for hydraulic conductivity (HC) and infiltration rate (IR) associated with the likelihood of substantial losses in permeability. Adapted from Oster JD and Jayawardane NS (1998). *Agricultural management of sodic soils*, p. 143–165. In Sumner ME and Naidu R (eds.) *Sodic Soils*. Oxford University Press.

The USSL Staff (1954) empirical method has gained worldwide popularity because of its simplicity and has been used extensively to predict ESPs of Na affected soils, even in recent years. However, Kopittke et al. (2006) in Levy (2012) stated that the relationship between SAR and ESP is not constant because preference for Na varies depending on the type of soil clay mineralogy and ionic strength; hence, this relationship should be determined directly for the soil of interest.

To date, there is no widely accepted definition of a sodic soil. The USSL Staff (1954) defined sodic soils as those whose physical properties are adversely affected by the presence of Na and suggested that an ESP of 15 should separate sodic from non-sodic soils. The USSL Staff (1954) added the reservation that this limit must be regarded as somewhat arbitrary and tentative. McNeal and Coleman (1966), supported use of $\text{ESP} > 15$ for defining sodic soils, but added that the electrolyte concentration in the percolating solution must exceed $3 \text{ mmol}_c \text{ L}^{-1}$ for this to hold true. Others (e.g., Levy et al., 2005), advocated that soils with $\text{ESP} > 5$ either exposed to solutions with total electrolyte concentration (TEC) of $0.7 \text{ mmol}_c \text{ L}^{-1}$ or being calcareous should be considered as sodic soils. The above critical ESP levels were based on hydraulic conductivity measurements, but studies on soil susceptibility to aggregate slaking (Levy, 2012), seal formation, runoff and soil loss (Kazman et al., 1983) have revealed that soils can exhibit sodic behavior at ESPs of 2–4. In view of the continuous effect of Na on soil behavior, from low to high ESP and TEC levels, no satisfactory decision or critical level of ESP can be recommended. Hence, Rengasamy et al. (1984) suggested that the “non-sodic” group of soils may be better classified as “low-sodic,” considering that dispersive effects may be present.

Moreover, as will be shown later, the interrelationship between ESP of the soil or SAR of its equilibrium solution, and the TEC of the soil solution, is important in dictating whether sodic or non-sodic behavior will be observed. This approach was used by Oster and Jayawardane (1998) to assess soil hydraulic conductivity and infiltration rate when exposed to waters with different TEC values (expressed in terms of electrical conductivity [EC]) when applied to soils with SAR values in the range of 0–60 (Fig. 1).

Origin and distribution of sodic soils

For most sodic soils, sodicity is a natural phenomenon related to the type of parent material and subsequent pedogenic processes. However, there are also sodic soils where sodicity arises from anthropogenic processes, which is termed secondary sodification. Irrigation without proper drainage, forest clearing, and other land management practices that can lead to waterlogging are the main human activities that cause rapid secondary sodification. It is expected that secondary sodification of soils will increase considerably in the future.

Data compiled by Wansik et al. (2016) indicates that sodic soils cover 581 million ha worldwide. The largest areas of sodic soils are concentrated in Australia (340 million ha) followed by north-central Asia (120.1 million ha) South America (59.6 million ha), Africa (27 million ha), Europe (22.3 million ha) and North America (9.6 million ha).

The spatial distribution of sodic soils demonstrates that they occur under a range of climates. Among the environmental conditions that promote the formation of sodic soils are the presence of shallow saline groundwater, the occurrence of perched watertables within 1 m of the soil surface, impeded drainage, low slope gradients, and textural discontinuities during deposition of sediments such as eolian, glacial or alluvial materials (Bui et al., 1998, in Levy, 2012).

The distribution of sodic soils and the conditions promoting their formation are based on a pedological or morphological approach. By contrast, a more useful definition of sodic soils is based on land management considerations. Many agricultural soils that exhibit sodic behavior may not fit into the classical sodic soil group, because typical morphological features including columnar subsurface structure are absent. Consequently, the large areas that these soils cover remain essentially unaccounted for.

Mechanisms responsible for sodic behavior

Among the various soil constituents, the fraction that determines the physical behavior of soils is mainly colloidal clay. Compared with other soil constituents, the clay fraction possesses a large specific surface area (per gram of clay), which combined with its charge make it a very reactive soil constituent in physico-chemical processes, mainly swelling and dispersion. These two processes largely determine the microstructure of the soil, thus significantly affecting many of its physical properties (Shainberg and Letey, 1984).

Clay swelling

Swelling takes place on wetting in smectite type clays, represented most commonly in soils by montmorillonite. Repulsive forces (swelling pressure) that can be predicted from the diffuse double layer (DDL) theory are responsible for the swelling (van Olphen, 1977, in Shainberg and Letey, 1984); their magnitude depends on the TEC of the ambient solution and degree of sodicity. When saturated with Na ions and in the presence of a dilute solution, a diffuse (wide) DDL forms creating high swelling pressures between the clay platelets, resulting ultimately in dispersion (see discussion below) of the platelets (Shainberg et al., 1971 in Shainberg and Letey, 1984). Conversely, low swelling pressures are observed between Ca-saturated platelets because strong forces of electrical attraction between Ca and the clay surfaces (not considered by the DDL theory) prevent complete swelling of Ca montmorillonite, even in deionized water. Instead, Ca platelets aggregate into tactoids or quasicrystals consisting of 4–9 platelets each. Moreover, in mixed Na–Ca systems, the ions are not randomly distributed throughout the system as was previously thought, but are located preferentially on inner and outer surfaces, respectively (Shainberg and Otoh, 1968 in Shainberg and Letey, 1984). This phenomenon is called ion demixing. Shainberg et al. 1971 in Shainberg and Letey (1984) demonstrated that clay swelling is limited at $ESP < 15$ because of demixing; as ESP increases further, a sharp increase in macroscopic swelling occurs as Na enters the tactoids.

Clay dispersion

Unlike swelling, a continuous and reversible process, clay dispersion, the separation of clay tactoids to single platelets, is not continuous and may even occur at low ESP values if TEC of the ambient solution is lower than a critical flocculation concentration (CFC) (Shainberg and Letey, 1984). Dispersion is an irreversible process because flocculation by increasing the TEC does not result in the original particle associations and orientations. A schematic illustration of the difference between dispersion and swelling is presented in Fig. 2.

Among the main clay minerals in soils, illite is the most sensitive to dispersion. The TEC required to prevent Na-illite from dispersing is $40\text{--}50\text{ mmol}_c\text{ L}^{-1}$, while for Na-montmorillonite a TEC of $12\text{--}16\text{ mmol}_c\text{ L}^{-1}$ is needed. For kaolinite systems no single TEC value can be used as a threshold value for preventing dispersion. Sodium saturated kaolinite will not disperse even in a salt-free solution provided solution-pH < 7 . With increasing pH, the positive charge on the edges of kaolinite particles is gradually eliminated and the kaolinite system becomes increasingly dispersive (Levy, 2012 and references cited therein).

Clay dispersion is affected not only by the presence of Na but also by the type of divalent cation. The presence of Mg enhances clay dispersion more than Ca in soils with mixed mineralogy (Ali et al., 1987 in Levy, 2012), and in kaolinitic and illitic soils.

Fig. 2 Changes in the structure of a clay domain from a stable state to swelling state and to dispersion. Adapted from Bennett J, Marchuk A, Marchuk S and Raine SR (2019) Towards predicting the soil-specific threshold electrolyte concentration of soil as a reduction in saturated hydraulic conductivity: The role of clay net negative charge. *Geoderma* 337: 122–131.

Fig. 3 Schematic illustration of the processes and intensity of attractive and repulsive forces involved when a dry soil aggregate is wetted, based on (Rengasamy and Sumner, 1998). Reprinted from Qadir M, Oster JD, Schubert S, Noble AD and Sahrawat KL (2007) Phytoremediation of sodic and saline-sodic soils. *Advances in Agronomy* 96: 197–247.

Furthermore, aggregates saturated with Na and Mg disperse at lower ESPs than those saturated with Na and Ca (Ali et al., 1987 in Levy, 2012).

Swelling and dispersion of soil clays differ significantly from that of pure clay systems, possibly because soil clays usually occur as mixtures and because of their association with other minerals, oxides and organic matter in the soil. It has been demonstrated that the TEC required for preventing dispersion of soil clays is 2–10-fold higher than that for pure clays (Frenkel et al., 1992). On the other hand, the presence of hydrous oxides or sparingly soluble minerals such as CaCO_3 has resulted in lower soil clay dispersivity. Thus, extrapolation of sensitivity to dispersion from pure clay systems to soil systems may often prove problematic.

The classical theory of DDL repulsive forces and van der Waals attractive forces developed for colloidal systems cannot satisfactorily explain clay dispersion following the disintegration of soil aggregates on wetting. Thus, a schematic 4-stage model was proposed by Rengasamy and Sumner (1998) to explain swelling and dispersion of soil clay particles (Fig. 3). Initially, when dry aggregates are wetted hydration of the adsorbed cations leads to swelling. Further hydration leads, in the case of highly sodic soils, to spontaneous dispersion, while for soils containing predominantly divalent cations mechanical separation is needed to disperse the clay. Dehydration of the dispersed system and buildup of osmotic pressure by increasing the electrolyte concentration leads to flocculation of the dispersed particles (Fig. 3).

Structural stability of sodic soils

Soil structural stability is the ability of the soil to retain its arrangement of aggregates and pores when exposed to different stresses. One of the most common properties used to characterize soil structure stability, especially against forces applied by water, is aggregate stability.

Aggregate breakdown by water may result from several physical and physico-chemical mechanisms. These include: (i) slaking, i.e., breakdown caused by compression of entrapped air during fast wetting; (ii) breakdown by differential swelling during fast wetting; (iii) breakdown by impact of raindrops; and (iv) physico-chemical dispersion due to osmotic stress upon wetting with low electrolyte water (Levy, 2012 and references cited therein).

Sodicity and aggregate stability

The effects of exchangeable Na in enhancing aggregate breakdown may occur by weakening the covalent associations between organic materials and soil minerals, and/or by increasing the osmotic/hydration forces that can cause particle repulsion during wetting.

Direct measurements of the effects of sodicity on aggregate stability have yielded inconclusive results. Some studies covering a wide range of soil texture (e.g., Alaboz, 2021) observed no correlation between aggregate stability and level of soil sodicity. Other studies have suggested that macroaggregate disintegration was affected only by $\text{ESP} > 10$, yet Crescimanno et al. (1995) in Levy (2012) noted that $\text{ESP} \leq 6$ could already have an adverse effect on aggregate stability, especially in fine-textured soils. Conversely, in the presence of Al and Fe oxides high ESP and low EC have only a small effect in promoting aggregate breakdown and clay

dispersion. Ruiz-Vera and Wu (2006) suggested that the response of aggregate stability to sodicity depends on clay mineralogy and content, and the rate at which the aggregates are wetted.

Role of organic matter

Soil organic matter (OM) comprises about 1–10% of a typical soil's mass of which 1–5% is microbial biomass (Nelson and Oades, 1998). Organic matter acts both as a bonding and dispersing agent in soils. The balance between these opposing effects depends upon the nature of the organic materials and their types of interaction with inorganic colloids. Because of the importance of organic matter in controlling soil structural stability, its involvement in aggregate breakdown under sodic conditions deserves a specific discussion.

Large amounts of soil-borne or added OM seem to promote resistance to sodic conditions. An inverse relationship has been noted between soil instability (inferred from modulus of rupture) and soil OM content at a wide range of ESP (Clark et al., 2009), especially for soils containing 10–20% clay. The favorable effects of organic agents on aggregate stabilization can be explained by nonionic bonding mechanisms by which roots, hyphae and natural polysaccharides stabilize aggregates, and which are not always directly affected by interactions between water, clay and exchangeable cations. An additional mechanism proposed for improving aggregate stability by SOM in sodic soils was the accumulation of cations such as Ca^{2+} , Mg^{2+} and K^+ and the increased leaching of Na^+ leading to low ESP in such soils.

The optimal dose of compost or other organic amendments to be applied to sodic soil ($\text{ESP} > 20$) for recovery of soil physical, chemical, and biological properties ranges from 10 to 50 t ha⁻¹ for different organic amendments (Leogrande and Vitti, 2019 and references cited therein). However, high rates of organic amendments (greater than 50 t ha⁻¹), even if useful to reduce soil sodicity, may cause increases of soluble salt concentrations and the accumulation of heavy metals or organic pollutants in the subsoil and/or groundwater (Leogrande and Vitti, 2019).

The more persistent SOM components including polyanionic colloidal materials (plant remains and microbial products), often referred to as humic substances, may adversely affect the stability of smaller scale aggregates (microaggregates) through a variety of mechanisms, but especially through their dispersing power. Organic anions can increase clay dispersivity, in particular when variable charge minerals are present mainly by increasing the negative charge density of the soil colloid fraction (Frenkel et al., 1992). Because humic substances form chelates with Ca, the effective SAR of the soil solution increases, and clay dispersion is promoted. There are also indications that the addition of humic fractions from a variety of sources (permanent pasture soil, cattle manure, and raw oxidized coal) could improve aggregate stability even in highly sodic soils ($\text{ESP} = 17$) (Imbufe et al., 2005 in Levy, 2012).

Water flow in sodic soils

Sodicity related degradation of soil structure leads to deterioration in soil water transmission properties. Water flow in the soil profile is commonly characterized by its hydraulic conductivity (HC), while water flow into the soil is characterized by its infiltration rate (IR). A distinction between HC and IR is made because a thin seal forms at the soil surface when water flows into the soil due to considerable disturbance from external forces, e.g., rain drop impact. Consequently, properties of the seal (or crust) differ from those of the underlying soil, and its thickness is difficult to measure, which makes the determination of its HC extremely difficult compared with a direct measure of its IR. Accordingly, the impact of sodicity on HC and IR are discussed separately.

Hydraulic conductivity (HC)

The HC of a soil depends on its properties and those of the percolating fluid. Several models have been proposed to describe the relations between the structure of a porous material, reflected by its pore size distribution, and its permeability. These types of models have failed to predict soil HC adequately, largely because they do not take into account the effect of fluid properties on the soil matrix geometry. Swelling and dispersion of clay in response to sodic conditions and the level of TEC in the percolating solution change the size of the conducting pores and hence affect the HC (Levy, 2012 and references cited therein).

Sodicity and electrolyte concentration

The realization that soil HC depends on both the SAR and TEC of the percolating solution, led to the development of the “threshold concentration” concept (Quirk and Schofield, 1955 in Shainberg and Letey, 1984) for defining the TEC required to prevent a decrease of usually >25% in the HC for a given soil ESP or SAR of the percolating solution (Fig. 4). This concept has been tested and validated on a large variety of soil types (e.g., Bennett et al., 2019) exposed to water of low salinity (e.g., rain or snow water), and explains decreased HC in soils, even Ca-soil and soils of low ESP. The decrease in HC is because salt concentration in the soil solution is not sufficient to prevent swelling and clay dispersion. Conversely, the Israeli experience in commercial fields showed that for Na-affected soils, irrigation with water having an SAR value as high as 26 with an electrical conductivity of 4.6 dS m⁻¹ exhibited no permeability problems because the electrolyte concentration in the irrigation water was sufficient to prevent the dispersive effect of Na (Shainberg and Letey, 1984). However, on applying electrolyte free water (to simulate rain water in winter), soil HC decreased

Fig. 4 Combinations of salt concentration and exchangeable sodium percentage required to produce a 25% reduction in hydraulic conductivity for selected soils. From McNeal BL and Coleman NT (1966) Effect of solution composition on soil hydraulic conductivity. *Soil Science Society of America Proceedings* 30: 308–312.

to a small fraction of its initial high value. Similar problems in HC arising from a decrease in TEC of the percolating water have been reported for soils mainly from semi-arid and arid zones. It was noted, however, that maintaining TEC of $10 \text{ mmol}_e \text{ L}^{-1}$ was not enough in many cases to prevent a decrease in HC for solutions with $\text{SAR} \sim 5$ (Suarez et al., 2008 in Levy, 2012).

A distinction should be made between effects of clay swelling and those of clay dispersion on the HC of soils. Soils begin to swell as the TEC of the soil solution is reduced, but the effect of swelling on HC becomes apparent only at SAR values above 10 in medium- and heavy-textured soils. In light textured soils the effect of swelling on reducing the conducting pores and hence HC is hardly noticeable. Furthermore, the swelling process is reversible, thus an increase in HC can be noted following an increase in TEC of the soil solution. Clay dispersion, on the other hand, can take place at low ESP levels provided the TEC is below a critical level. When clay dispersion occurs, the dispersed clay particles move down the soil profile and may even cause a complete blockage of the conducting pores, and hence an irreversible change in the HC (Shainberg and Letey, 1984). Consequently, the effects of reducing TEC on the HC are likely to be more severe when clay dispersion rather than swelling, is the predominant cause.

Soil properties affecting sodic behavior

The response of soils to sodic conditions varies among soils, mainly because soil properties have a significant effect on the dependence of the HC on sodicity. A major factor causing differences among various sodic soils in their susceptibility to hydraulic failure when leached with water of low TEC was their rate of salt release from mineral dissolution. Mineral dissolution determines the electrolyte concentrations of percolating solutions and hence soil HC. Sodic soils containing minerals (CaCO_3 and a few primary minerals) that readily release soluble electrolytes will not readily disperse when leached with deionized water (DW) at moderate ESP values, because a sufficiently high electrolyte concentration ($\sim 3 \text{ mmol}_e \text{ L}^{-1}$) could be maintained to prevent clay dispersion. In addition, ESP values will decrease, because most of the cations released are Ca and Mg. Conversely, soil solution concentrations in soil lacking readily weatherable minerals are likely to be below the critical TEC required for preventing dispersion, making the soils more susceptible to clay dispersion and reduction in HC (Shainberg and Letey, 1984).

Clay content, through its effect on pore-size distribution, contributes significantly to the response of soils to sodic conditions. The sensitivity of HC to sodic conditions is generally greater for soils with medium and high clay content. When clay content is high, clay swelling may significantly reduce the size of water conducting pores and lead to low HC. Similarly, under dispersive conditions the dispersed clay particles clog the pores and cause a reduction in soil HC. Conversely, in sandy soils, due to the low clay content, clay swelling has only a limited effect on the HC. Conditions supporting clay dispersion in these soils may cause HC first to decline

and subsequently to recover. This phenomenon is explained by the change in flow pattern from a solution flowing through a matrix of sand covered with clay, which starts to disperse and reduce HC to the flow of a clay suspension in a pure sandy matrix with large pores resulting in a subsequent increase in HC (Pupisky and Shainberg, 1979 in Shainberg and Letey, 1984). More recently, Levy et al. (2005) noted that the response of soils' HC to the combined impact of clay content and soil ESP on the HC is difficult to predict. Clay content acts as a cementing agent, hence higher clay content supports more stable aggregates and prevents the decrease in HC. Conversely, the greater the clay content the more effective is clay swelling in narrowing the water conducting pores. Changes in soil ESP affect soil swelling and dispersion. The reliance of HC on both factors depends on the relative weight of each of these factors in determining the mechanism that affects HC (Levy, 2012).

The role of soil OM and, especially its labile fraction, water extractable OM (commonly termed dissolved organic matter [DOM]), in determining soil sensitivity to sodicity has recently gained much interest. The reason for that lies in the increasing use of treated wastewater for irrigation of cultivated lands. Unlike fresh water, TWW contains DOM, the amount of which depends on the treatment the TWW had been subjected to, and higher SAR than its original fresh water. The relation between soil solution sodicity (SAR) and DOM are complex. Concentration of DOM and specific ultra-violet absorbance (SUVA) were significantly higher at SAR 20 than at SAR < 3 in combination with low TEC (Mavi et al., 2012). In turn, increased concentration of dissolved organic molecules may complex more Ca^{2+} and Mg^{2+} cations that lead to an increase in the effective SAR of the soil solution, which would finally contribute to a decrease in soil HC. Reports of differences of 48% between SAR and effective SAR were attributed to a greater affinity of divalent cations to organic ligands. The direct effect of DOM on water flow in soil was considered to be equivalent to an increase in SAR of 2–3 units (Suarez and Gonzalez-Rubio, 2017). Yet, in soils containing available Ca (e.g., calcareous soils), the affinity of the soil to Na decreases with the increase in DOM concentration, suggesting that DOM diminishes the adverse effects of Na on the soil (Assouline et al., 2016).

Other soil properties that may affect the response of soils to sodic conditions include:

1. Presence of aluminum and iron oxides—these oxides commonly occur in highly weathered soils and enhance, via cementing action, soil stability, and substantially decrease its susceptibility to sodic conditions.
2. Clay mineralogy—soil with high content of 2:1 layer silicates (e.g., montmorillonite) are the most labile ones while those high in kaolinite and sesquioxides are the least labile.
3. Exchangeable Mg—although in many soils the exchangeable Ca/Mg molar ratio is high, but in others the reverse is true. Effect of adsorbed Mg on soil hydraulic properties seems to depend on soil type. In calcareous soils, the presence of Mg enhanced the dissolution of CaCO_3 producing electrolytes that prevent clay dispersion and HC decay, while in noncalcareous soils Mg causes a decrease in the HC of the soils beyond that of the Na/Ca system. Exchangeable Mg can cause a direct (“specific”) effect and decrease in HC, whereas Mg in irrigation water cannot counter the accumulation of exchangeable Na in the soil.

Sodicity and conditions prevailing in the soil

It has been recognized recently that soil response to sodic conditions depends not only on soil properties but also on the conditions prevailing in the soil such as antecedent moisture content, wetting rate, and wetting and drying cycles (Hamilton et al., 2007). Soil conditions affect aggregate stability/breakdown and thus pore-size distribution and consequently the HC. Aggregate breakdown results from dispersion and slaking during wetting, whose rate determines the degree of slaking. It was reported that the HC of sodic soils leached with DW decreased more steeply and to lower values with an increased rate of wetting. Fast wetting, which increases aggregate slaking, increased the susceptibility of soil to sodic conditions. Conversely, slow wetting decreased significantly the effects of sodicity on soil HC, especially in fine-textured soils (Fig. 5).

Infiltration rate

Soil infiltration rate (IR) is defined as the volume flux of water flowing into the profile per unit of soil surface area under any set of circumstances. Often, when water is supplied to the soil the IR decreases from its initial high rate due to the formation of a thin seal (<2 mm) at the soil surface. A structural seal, usually caused by raindrop impact, should be distinguished from a depositional seal formed by translocation and deposition of fine soil particles at a certain distance from their original location. The discussion to follow will focus on structural seals.

Sensitivity of seal formation and IR of a smectitic loamy sand to ESP when exposed to deionized water under laboratory simulated rain is presented in Fig. 6. Even at the lowest sodicity (ESP 1.0), a seal was formed and the IR decreased from an initial value >100 to a final infiltration rate (FIR) of 7.0 mm h⁻¹. An ESP value of 2.2 was sufficient to cause a further decrease in the final IR of the sandy loam to 2.4 mm h⁻¹. The amount of rain required to approach the FIR (i.e., the rate of seal formation), was also affected by sodicity (Fig. 6). As the energy from raindrop impact was the same in all experiments, the differences in IR curves for the various treatments were the result of chemical dispersion of the soil clay caused by sodicity. The sensitivity of the soil surface to low ESP values is explained by (i) the mechanical impact of the raindrops, which enhances chemical dispersion, and (ii) the almost total absence of electrolytes in the applied deionized water (Shainberg and Letey, 1984). With respect to (i), it has been noted that in the lower range of ESP the chemical mechanism needs some activation energy to start operating at the soil surface, which, in the case of rain is provided by raindrop impact. Conversely, in the absence of mechanical impact, the chemical mechanism does not come into effect at low ESP levels (<5) (Shainberg and Letey, 1984).

In cases where soil is exposed to overhead irrigation (e.g., sprinklers, moving irrigation line), IR is sensitive to both the TEC and SAR of the water applied. The lower the concentration of the electrolyte solution, the faster is the rate at which the IR decreases. For similar electrolyte concentrations, increasing soil ESP leads to a sharper decrease in and a lower final IR. Increasing TEC greatly increased the IR even at low ESPs of 1–2. For example, in Californian soils final IR increased from 2 to 28 mm h⁻¹ as cation concentration in the applied water with SAR <5 increased from 5 to 28 mmol_cL⁻¹. These results, and others, indicate that IR is far more sensitive than HC to both SAR and electrolyte concentration of the applied water (Levy, 2012).

Although Ca and Mg are both divalent cations, their effects as the complementary cation to Na, on IR may differ. At high energy rain (>20 kJ m⁻³) exchangeable Mg had an effect similar to that of Ca, but at low to medium energy (8.0–12.5 kJ m⁻³), the IR in Mg–Na soil was lower than that in the Ca–Na soil. These findings suggest that the adverse effect of Mg on IR is pronounced only under conditions where chemical dispersion is dominant in controlling IR, i.e., raindrops with low to medium kinetic energy (Keren, 1990 in Levy, 2012).

The susceptibility of sodic soils to seal formation and reduction in IR depends to a large extent on clay content. Soils with 10–30% clay are perceived as the most susceptible to seal formation and have the lowest IR. With increasing clay content, soil structure becomes more stable and seal formation diminishes. In soils with lower clay contents (<10%), the amount of clay available to disperse and clog soil pores is limited and, as a result, a poorly developed seal is formed (Levy, 2012).

Similar to HC, it has recently been recognized that the IR of sodic soils depends not only on soil properties but also on the prevailing conditions such as rate of aggregate wetting, antecedent moisture content (AMC) in the aggregates and aging duration (e.g., Kjaergaard et al., 2004 in Levy, 2012). This dependence is, however, greater in fine textured soils than in coarse ones.

Fig. 6 The effects of the soil exchangeable sodium percentage (ESP) and phosphogypsum application on the infiltration rate of the sandy (Hamra Netanya, Israel) soil as a function of the cumulative rain. From Kazman Z, Shainberg I and Gal M (1983) Effect of low levels of exchangeable Na and applied phosphogypsum on the infiltration rate of various soils. *Soil Science* 35: 184–192.

Soil erosion

A strong relation between dispersible clay, IR and soil loss has been reported in numerous studies (Levy, 2012). The IR for soils from different regions of the world decreases as SAR and ESP increase, making more water available for runoff which, in turn, tends to increase erosion (Sumner, 1993, in Rengasamy and Sumner, 1998). Recently, Mamedov and Levy (2019) suggested that under sodic conditions, erosion by water increases exponentially with the increase in runoff compared with a linear relation between these in non-sodic soils. Levy et al. (1994) in Levy (2012), however did not observe a direct relationship between soil ESP, IR and erosion. They argued that with an increase in ESP the IR decreases, but the resulting erosion depends on the balance between the larger volume of runoff and a more dense and structurally more resistant seal; thus the amount of erosion cannot be predicted based on runoff volume only. Enhanced clay dispersivity associated with sodic conditions in the soil can lead not only to surface but also to subsurface erosion processes such as piping and tunneling, which may lead to the formation of deep gullies that further enhance erosion, mainly in kaolinitic and illitic soils.

Sodicity and soil productivity

Productivity of sodic soils is limited, mainly because the deterioration in their physical properties which causes poor aeration, restricts root development and enhances root diseases. These not only decrease crop yields but also limit the choice of crops that can be grown. For a detailed review of crop response to sodicity and sodicity-related fertility and nutritional constraints, readers are referred to Curtin and Naidu (1998).

Crop tolerance to sodicity

Research on crop tolerance to sodicity has been conducted under two types of condition, in the presence or absence of sodicity-related adverse soil physical conditions. Studies on crop tolerance to sodicity based merely on nutritional factors have indicated that at relatively low ESP values (2–10) some crops show signs of sodium toxicity (Pearson, 1960); however, most field crops are classified as moderately tolerant or tolerant to sodicity (Table 1). Conversely, studies carried out under conditions where soil structure was allowed to be affected by sodicity reported grasses as being tolerant, wheat (*Triticum aestivum* L.) and barley (*Hordeum vulgare* L.) being moderately tolerant, and peas (*Pisum sativum* L.) and beans (*Phaseolus vulgaris* L.) being sensitive to sodicity (Gupta and Abrol, 1990). Recently, Garg et al. (2005) observed that fennel (*Foeniculum vulgare* Mill) was tolerant to sodicity to ESP of 25. Use of the concept where the soil is allowed to be affected by sodicity may, however, cause results to be site specific and hinder their applicability to other locations and soil types. Thus, ranking of crops for sodicity tolerance depends on the conditions under which the response was determined.

Table 1 Tolerance of various crops to exchangeable sodium.

Tolerance to ESP ^a	Crop
Extremely sensitive (ESP 2–10)	Deciduous fruits Nuts Citrus Avocado (<i>Persea Americana</i> Mill)
Sensitive (ESP 10–20)	Beans (<i>Phaseolus vulgaris</i> L.)
Moderately tolerant (ESP 20–40)	Clover (<i>Trifolium</i> L.) Oats (<i>Avena sativa</i> L.) Tall fescue (<i>Festuca arundinacea</i> Shreb.) Rice (<i>Oryza sativa</i> L.) Dallis grass (<i>Paspalum dilatatum</i> Poir.)
Tolerant (ESP 40–60)	Wheat (<i>Triticum aestivum</i> L.) Cotton (<i>Gossypium hirsutum</i> L.) Alfalfa (<i>Medicago sativa</i> L.) Barley (<i>Hordeum vulgare</i> L.) Tomatoes (<i>Solanum lycopersicum</i> L.) Beets (<i>Beta vulgaris</i> L.)
Most tolerant (ESP >60)	Crested and fairway wheatgrass (<i>Agropyron cristatum</i> L.) Tall wheatgrass (<i>Thinopyrum ponticum</i> , (Podp.) Z.-W. Liu & R.-C. Wang) Rhodes grass (<i>Chloris gayana</i> Kunth)

Plant nutrition in sodic soils

Field fertility studies carried out in sodic soils often yield inconclusive results, mainly due to considerable spatial variation. Consequently, most dependable data on sodicity-related nutritional aspects have been obtained from greenhouse and laboratory studies (Levy, 2012).

Nitrogen, phosphorus, and potassium are the most important nutritional elements. Phosphorus and potassium, generally do not pose a nutritional problem in sodic soils. Conversely, nitrogen (N) can limit plant growth in many sodic soils because of low rates of N mineralization, denitrification under restricted aeration conditions, volatilization of NH_3 under alkaline conditions, and inhibition of NO_3 uptake by Cl or SO_4 ions which are usually abundant (Grattan and Grieve, 1999).

Plants growing in sodic soils may also suffer from impaired Ca uptake. The ratio of Ca to total cation concentration (TCC) is considered a better indicator of Ca availability to plants than actual Ca concentration. Carter and Webster (1990) found that Ca/TCC ratios <0.1 often occur in saturated paste extracts of sodic soils, which for many crops would result in Ca deficiency. In addition, high Mg/Ca ratios, often found in sodic soils, can also cause Ca deficiency.

Furthermore, extreme ratios of Na:K, Mg:Ca, and $\text{Cl}:\text{NO}_3$ (Grattan and Grieve, 1992 in Levy, 2012) are likely to be found in the soil solution of sodic soils. Such ratios, rather than absolute values, may lead to salt-stressed plants, specific-ion toxicity, and nutritional disorders.

Reclamation and management of sodic soils

Management of sodic soils, involving the improvement in soil structure (to alleviate problems of water permeability and logging, erosion, inadequate aeration, compaction, etc.), is essential if long-term productivity is to be maintained. Several site-specific approaches involving the use of chemical amendments, organic waste materials, tillage, crop diversification, have been used to ameliorate sodic soils.

Chemical amelioration

The most common concept for reclamation of sodic soils advocates the addition of divalent cations to the soil to replace exchangeable Na. There are two common practices: (i) use of chemical amendments that release Ca ions to the soil, and (ii) application of successive dilutions of a high salt water containing divalent cations.

Chemical amendments

Typical amendments are those containing a source of soluble Ca or that dissolve Ca upon reaction in the soil. Common amendments include gypsum, lime, CaCl_2 , sulfuric acid, and sulfur (Levy, 2012 and references cited therein).

Gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), both from geological and non-geological sources (industries that produce CaSO_4 by-products) is the most commonly used amendment for the reclamation of sodic soil primarily because of its low cost, reasonable solubility and availability. Gypsum added to a sodic soil can increase aggregate stability and permeability by both TEC and cation-exchange effects. If gypsum is used to maintain high permeability at the soil surface during the application of good quality water, i.e., rainwater or other sources of water with low TEC, then the electrolyte effect is important. In this case, surface application of gypsum may be worthwhile, and the dissolution rate of gypsum dictates whether the rate of electrolyte supply to the water is sufficient to prevent clay dispersion and swelling. Thus, because of its higher rate of dissolution, gypsum from industrial sources such as by-products of the phosphate (phosphogypsum) and power generation (flue gas desulfurization gypsum) industries is preferable to mined gypsum. In this case, the amount of gypsum required depends on the amount of high quality water applied and the rate of gypsum dissolution, and is relatively independent of the amount of exchangeable Na in the soil profile (Levy, 2012).

Cation exchange effect is important in soils where treating high ESP of the soil profile is important. The amount of gypsum required depends then on that of exchangeable Na in a selected depth of soil. Amount of exchangeable Na to be replaced per unit land area (Q_{na} , mole_c ha⁻¹) during reclamation depends on the initial and desired final exchangeable Na fraction, cation exchange capacity of the soil, its bulk density and depth of soil to be reclaimed. Thus, the amount of gypsum needed to reclaim the soil, termed "gypsum requirement" (GR) is calculated as follows (Oster and Jayawardane, 1998):

$$\text{GR} = (8.61 \times 10^{-5}) Q_{\text{na}} \quad (7)$$

Efficiency and rate of exchange, namely percentage of Ca that exchanges for adsorbed Na, varies with ESP, being much greater at initial high ESP values.

Successive dilutions of high salt water

In areas where water is not a limiting factor, reclamation of sodic soils can be achieved by leaching the soil with successive dilutions of water with a high salt content containing divalent cations. In the early stage of the leaching, the high TEC in the applied water prevents clay dispersion and induces flocculation of the soil colloids. Simultaneously, the Ca ions in the water decrease sodicity by replacing exchangeable Na. Upon dilution of the saline water with high quality water, the SAR of the water is reduced. To ensure successful soil reclamation, depth of water added should be at least nine times the depth of soil to be reclaimed.

Problems associated with this method include (i) use of water containing inadequate concentration of divalent cations, (ii) the need to develop facilities that collect, convey and treat the saline water, and (iii) the need to dispose of the highly saline-sodic drainage water in such a way that soil, and surface and groundwater contamination are avoided (Qadir et al., 2007).

Amendment with organic wastes

In addition to chemical ameliorants, soil amendments can include organic wastes (fresh or composted) such as farm manure and plant residues that contribute to the stabilization of soil aggregates. Addition of these organic ameliorants is a widely recognized practice for managing cultivated sodic soils. Application of organic matter is most effective in ameliorating alkali (soils with high pH) sodic soils. However, its ameliorative effects are generally restricted to the surface horizons where organic matter inputs tend to be concentrated (Nelson and Oades, 1998). Because successful amelioration with organic materials must involve leaching, irrigation must be frequent and in small amounts. Under rainfall, amelioration with organic wastes can be expedited by minimizing runoff and evaporation, and increasing infiltration.

Furthermore, biologically ameliorated sodic soils must be cropped continuously. Rice is commonly used especially in the initial stages of reclamation because of its tolerance to sodicity, and also waterlogged conditions favor reclamation. When cropping is not possible, pastures, green manure and agroforestry can also contribute to soil reclamation (Levy, 2012).

Tillage

Tilling sodic soils, which often results in improvements in physical and hydraulic properties, reduces bulk density and increases total porosity (especially macroporosity), improves internal drainage and saturated and unsaturated HC. Consequently, aeration is improved and plant growth is enhanced (Sadiq et al., 2007). However, the beneficial effects of tillage on sodic soils are often not long lasting because they tend to reconsolidate under their own weight when wetted, and the hydraulic properties deteriorate once more.

Deep tillage (1–2 m) or ripping breaks up hardpans and cemented layers, mixes soil layers and causes, in general, a permanent improvement in soil structure and physical properties. To obtain optimal results plowing should be carried out at the correct soil moisture content that may differ according to soil texture. Deep tillage can sometimes lead to water logging and infiltration problems by bringing sodic subsoil to the surface. Conversely, shallow tillage (disking or chiseling) is effective in reducing soil permeability problems associated with surface crusts, hardsetting and compaction. However, shallow tillage may require repetition from time to time.

A combined treatment of tillage and gypsum application, termed “gypsum slotting” has been developed in Australia. Gypsum is added to narrow slots (about 150-mm wide, 0.4-m deep and spaced about 1–2-m apart) created by tillage at rates sufficient to reclaim the soil in the tilled slot. The advantages include efficient removal of excess water from the surface layer and its storage in the subsoil for use during dry spells, reclamation of the soil in the slots, maintaining adequate macroporosity and increasing yields (Jayawardane et al., 1987 in Levy, 2012).

Remediation with vegetation

Qadir et al. (2007) have extensively reviewed amelioration of sodic soils using vegetation. Vegetative remediation treatments are effective largely through their effects on both the physical and chemical properties of sodic soils (Fig. 7). Crop roots can stimulate changes in physical properties of the root zone in several ways such as removal of entrapped air from larger conducting pores, generation of alternate wetting and drying cycles, and creation of macropores. Aggregate stability is enhanced because of in situ production of polysaccharides and fungal hyphae in conjunction with differential dewatering at the root-soil interface.

Instead of deep plowing, which at times could aggravate rather than improve soil conditions, vigorous rooted rotation crops can also alleviate subsoil compaction. An alternative to subsoil amelioration is the use of ridge instead of bed farming techniques. With ridges, the plants are ~0.25 m above the neighboring furrows, and aeration is improved, especially in heavy textured soils suffering from water logging in the subsoil (Hearn and Constable, 1984 in Levy, 2012).

Cropping in sodic soils affects the chemistry of the root zone environment, especially in calcareous soils. The following processes are involved: (i) enhancing the $p\text{CO}_2$, (ii) dissolution of CO_2 in water to form carbonic acid (H_2CO_3) and its immediate dissociation to proton (H^+) and bicarbonate (HCO_3^-), (iii) reaction of H^+ with soil CaCO_3 to produce Ca, (iv) Na–Ca exchange at the soil's cation exchange sites (v) leaching of the exchanged Na^+ in the percolating water and (vi) subsequent reduction in soil sodicity (Fig. 7).

Removal of aboveground biomass of plant species, used for phytoremediation of sodic and saline-sodic soils, removes salts and Na taken up by the plants and accumulated in their shoots (Qadir et al., 2007). Highly salt-resistant species such as halophytes may accumulate quite large amounts of salts and Na in their shoots. The efficiency of various plant species for ameliorating sodic soils varies, possibly due to differences in their tolerance to salinity which often accompanies sodicity. A summary of lysimeters and field experiments showed that vegetative remediation was somewhat less effective than chemical amelioration in reducing soil sodicity. This finding could be explained, at least in part, because crops used on sodic soils may experience oxygen deficiency especially when excessive irrigations are used to leach the soil. Thus, evaluation of crops for the amelioration of sodic soils should consider also their resistance against hypoxia (Qadir et al., 2007).

Fig. 7 Schematic illustration of driving forces for phytoremediation of calcareous sodic and saline-sodic soils. Reprinted from Qadir M, Oster JD, Schubert S, Noble AD and Sahrawat KL (2007) Phytoremediation of sodic and saline-sodic soils. *Advances in Agronomy* 96: 197–247.

Environmental aspects of sodic soils

Assessment of sodium related soil degradation has usually been carried out in the context of agriculture and soil productivity. However, sodic behavior of cultivated soils also poses numerous environmental hazards which are discussed below. Sodic soils may also have some environmental bearings on engineering and urban applications. Yet, they also present some opportunities for enhanced carbon sequestration in the soil.

Erosion and suspended sediments

Sodic soils are susceptible to clay dispersion and surface sealing, which generate runoff and cause erosion that poses a serious problem for crop production. About 40% or more of the sediments carried by runoff leave cultivated fields and reach streams or other water bodies, thus causing substantial negative effects to the environment. Moreover, large sediment and salt losses can occur in runoff from saline-sodic soils, even at low slopes and from apparently stable soils, with adverse consequences for downstream water quality. The sediments removed clog drainage ditches and irrigation canals, and decrease the capacity of water reservoirs, thus increasing maintenance costs. In addition, sediments damage or entirely destroy fish spawning areas. Sedimentation of rivers and streams reduces their capacity to carry water and increases the danger of flooding and consequent damage to property and to human health. It has been estimated that the cost of offsite damage from cropped land in the United States is in the range of \$2.2–13.5 billion annually (Tegtmeier, and Duffy, 2004).

The presence of suspended sediments in water, originating from eroded sodic soils, increases its turbidity. Turbid waters are less attractive for recreational activities and allow less sunlight to pass through, thus negatively affecting aquatic productivity. In addition, turbid water, which is denser than clean water, is more costly to pump. High turbidity in water bodies used for domestic consumption leads to extra costs in purification.

Salination and pollutants

Sodic soils commonly contain large amounts of salts that are transferred to nearby water bodies at a relatively fast rate when the soil is cultivated. Shallow saline–sodic watertables contribute significantly to the salt load of rivers. In addition, sodic soils often require proper drainage systems to remove water that is much more saline than the irrigation water. When this drainage water enters surface water, the quality sometimes deteriorates rendering it unsuitable for further use in irrigation, livestock watering or cities.

Salt accumulation resulting from sodic soil reclamation is an additional source for soil salination. Most reclamation activities require the addition of Ca salts (e.g., gypsum). Following exchange reactions in the soil, Na salts become dominant. In general, Na salts dissolve readily and are easily displaced downward into soil strata and groundwater beneath irrigated fields. Extensive reclamation can also cause shallow saline watertables which often require drainage. The saline drainage water ends up in surface water bodies, increases their salinity, and reducing their value. Therefore, reclamation of sodic soils may have some negative environmental consequences that should be carefully considered when planning and executing reclamation activities are considered.

Transport of various contaminants by soil colloidal materials suspended in runoff water to ground or surface water bodies poses a serious environmental hazard. Metals that are usually fairly immobile in soil and have strong affinity for soil colloids move together with the mobile colloids. Similarly, insoluble pesticides, herbicides, and some nutrients, e.g., P (Mamedov et al., 2020) have a strong affinity for soil colloids and can thus be transported with suspended solids to adjacent water bodies and groundwater. The increased concentration of suspended colloids in runoff water due to sodic conditions greatly increases the danger of higher than permitted loadings of these pollutants in ground and surface water bodies.

Carbon (C) sequestration

Sodic soils have lost a large fraction of their original C pool. The magnitude of the loss may range between 10 and 30 Mg C ha⁻¹, depending on the antecedent pool and the severity of degradation (Qadir et al., 2007). Amelioration of sodic soils may enhance C accumulation in the soil in both organic and inorganic forms.

Moreover, sodic soils commonly occur in arid and semi-arid regions where they generally contain large pools of primary (lithogenic) and secondary (pedogenic) inorganic carbonates (Lal, 2002). Dissolution of the carbonates in the root zone could result from the accumulation of high pCO₂ (root respiration and decomposition of organic matter) or by acidic root exudates. The resulting HCO₃⁻ can then be leached, especially under irrigation management, down the soil profile and its subsequent precipitation is a possible pathway for C sequestration in an inorganic form. It is estimated that C sequestration through this mechanism ranges between 0.25 and 1.0 Mg C ha⁻¹ year⁻¹.

Concluding comments

Sodium is present in many soils worldwide in amounts that may negatively affect their behavior. The area occupied by sodium-affected soils is expected to grow due to increased use of poor quality soils and water for agricultural production. The most important processes that occur in sodic soils, swelling and dispersion, adversely affect soil structure, and soil physical and hydraulic properties. The adverse effects of sodicity are inversely related to TEC of the irrigation water and soil solution. Soil sodicity enhances runoff, soil erosion and transport of contaminants that cause both on-site, (cultivated fields), and off-site (environmental) damage. However, sodium-related soil degradation and loss of productivity are, to a certain degree, reversible because sodic soils can be reclaimed. In addition, realization of the hazards of sodicity and consequent adoption of suitable management practices allow safe and sustainable use of sodium-affected soils, reducing the likelihood of their abandonment.

Abstract

Organic soils (Histosols) are formed by accumulation of incompletely decomposed organic matter. This chapter introduces the classification, genesis and properties of organic soils and potential management. Organic soils comprise histosols with folic horizons formed in cold climates as well as fens and bogs with or without contact with minerotrophic groundwater (mainly Rheic and Ombric Histosols, respectively). The soils have low bulk density and high water storage capacity, but may be limited by nitrogen, phosphorus, and other inorganic trace elements, particularly when plants lack contact with groundwater. Histosols cover 3% of the global land surface, but store 21% of terrestrial soil carbon.

Key points

- Organic soils form by the incomplete decomposition of plant remains.
- Organic soils comprise well aerated Folic Histosols as well as bogs and fens.
- Cold temperatures, terrestrialization and paludification are the main mechanisms of the formation of organic soils.
- Drainage and use of organic soils induce irreversible subsidence and carbon emissions.
- Restoration and paludiculture are sustainable land use options for organic soils.

Introduction

Organic soils store with 650 Gt carbon (C) 21% of the global soil organic C stock (Yu et al., 2010) and they can sequester another 0.1 Gt C annually (Frolking et al., 2011). However, they cover only 3% of the Earth's land surface. Nevertheless, areas with organic soils provide a unique habitat for many specialized and endangered species. Hence, organic soils are a key component of terrestrial feedbacks to biodiversity, global water, energy and matter cycles and thus to our climate system.

When biomass production exceeds decay, organic soil horizons and finally organic soils can be formed. Organic soils therefore cover a wide range of soil types under conditions promoting organic matter accumulation and inhibiting its decomposition. Hence,

organic soils are abundant in regions with cold temperatures, with water saturation or both. They are typically found in the subarctic and boreal regions of the northern hemisphere, in depressions and marshlands of the temperate zone, and in tropical lowlands. The organic horizons mainly comprise plant residues of different but incomplete stages of decomposition. The organic remains originate from various plant sources, including grasses, sedges, mosses or trees, with some additional contributions from, e.g., microbial necromass and black carbon. Due to the lack of stabilizing minerals, organic soils are vulnerable to changes in climatic conditions and management. The anthropogenic use of organic soils, for example, has been estimated to lead to almost 2 Gt of CO₂-eq emitted from drained organic soils only (Leifeld and Menichetti, 2018).

The classification system derived from the FAO (WRB; World Reference Base; IUSS Working Group WRB, 2015) defines organic soils as Histosols (Greek *histos*: tissue) with a diagnostic folic or histic horizon. These two diagnostic organic horizons may occur in other major reference soil groups, e.g., Cryosols, Leptosols, Podzols, where, however, they appear only as a single principle qualifier, which is not sufficient to categorize them as an organic soil. This is because, depending on clay content, the folic or histic horizons must also contain at least 12–18% organic C and have a minimum depth of either 10 cm when overlying rock or ice, or of 40 cm, when overlying mineral soil. In both cases the mineral matter does not influence soil properties significantly. Soils with a folic horizon (Folic Histosols) are well aerated and occur mostly in mountainous alpine areas and high latitudes where low temperatures reduce rates of decay. The vegetation period is short and biomass production is limited, so that folic horizons are frequently shallow. The organic matter composition usually differs from that of histic horizons because the vegetation cover is often different. Histic horizons are generally water-saturated for at least one or more months. Organic soils with a histic horizon are usually found in peatlands and can be several meters thick. There are two major types of peatlands: fens receive water and nutrients from groundwater and surface streams, while bogs are rain-fed and poor in nutrients (Fig. 1) (Box 1). The decomposition of organic

- Histosols with a *folic horizon* (Folic Histosols) overly bedrock or fragments and are naturally well drained. They receive their water and nutrient supply mainly from precipitation and are poor in nutrients and often acidic. They are found in cold regions in high latitudes or altitudes and the vegetation is mainly grasses, heathers and mosses while trees also grow on thicker Folic Histosols.
- Fens (e.g., Rheic, frequently also Eutric Histosols) are formed under high groundwater levels and can exhibit a wide range of pH and nutrient availability, depending on the type of bedrock. Fens with low pH and low nutrient availability (mesotrophic) support vegetation such as mosses and have a C:N ratio of 20–33, while nutrient-rich (eutrophic) fens have elders, sedges and reeds and a low C:N ratio of 10–20.
- Bogs (e.g., Ombric, frequently also Dystric Histosols) are fed solely by rainwater; thus, they are very acidic with pH values between 2.5 and 4. They are oligotrophic (nutrient-poor) and the C:N ratio is usually higher than 33. Highly specialized plant genera such as peat mosses (*Sphagnum*) and sundews (*Drosera*) live in bogs in temperate and boreal zones. In tropical bogs, the vegetation consists mainly of tall trees which have adapted to the low nutrient availability and anaerobic conditions.

material in peatlands is decelerated by water saturation and poor aeration in fens and in addition by acid conditions and limited nutrient availability in bogs.

All organic soils have distinct properties that distinguish them from mineral soils, such as large organic matter content, low bulk density, large pore volume and thus, large water storage capacity. Therefore, the agricultural use of organic soils is difficult and frequently unsustainable. Nevertheless, they are widely used for agriculture, forestry and peat extraction after drainage, which alters their physical and chemical properties, diminishes C storage and converts them into large C sources. In contrast to the conventional use, wet biomass cultivation (paludiculture) is one sustainable management option for organic soils.

Classification

There are non-uniform classifications for organic soils, some of which refer only to peat soils. Many countries use their own classification systems, which differ mainly in the thickness of the organic horizon and also in the required content of organic C. Here, we refer to the classification of the World Reference Base for Soil Resources (IUSS Working Group WRB, 2015) and also present Soil Taxonomy (United States Department of Agriculture, USDA). Both call organic soils Histosols (Table 1).

In the WRB classification, they are defined as soils having organic material which

- (a) starts at the soil surface, has a minimum thickness of 10 cm and directly overlies ice, continuous rock or coarse fragments of which the interstices are filled with organic material. Or
- (b) the organic material starts within the first 40 cm from the soil surface and has within the first meter of the soil a combined minimum thickness of either 60 cm if $\geq 75\%$ of the organic material is moss-derived or 40 cm in other organic material (IUSS Working Group WRB, 2015).

A further diagnostic criterion for Histosols is the content of organic C. The soil has to contain at least 20% organic C in the fine earth (by mass) or $(12 + [\text{clay percentage in the mineral fraction} \times 0.1])$ % or more organic C in the fine earth or at least 18% organic C in the fine earth if it is saturated with water for at least 30 consecutive days per year. Associated horizons with these properties are folic and histic horizons. Folic horizons are well aerated and water-saturated for less than 30 consecutive days per year. Histic horizons are, on the other hand, organic horizons which are poorly aerated and water-saturated for more than 30 consecutive days per year.

There are certain terms to describe the degree of decomposition of peat and other organic soils. 'Fibric' material is slightly decomposed, with 2/3 recognizable plant tissues. Amorphous organic material with less than 1/6 recognizable plant tissues is called sapric. 'Hemic' organic material is intermediate between fibric and sapric.

Unlike Histosols in the WRB classification, Histosols in the USDA Soil Taxonomy do not have permafrost or gelic materials within the first 100 cm. In addition, the suborder distinguishes between 'Folists' and 'Fibrists', 'Hemists' and 'Sapristis'. Folists represent freely drained organic soils where the organic matter overlies rock or fills its interstices. Fibrists, Hemists and Sapristis describe water-saturated organic soils with different degrees of decomposition, similar to the principal qualifiers fibric, hemic and sapric in the WRB classification. There, at least half of the material in the upper 80 cm is organic. If the bulk density is less than 0.1 g cm^{-3} , at least $\frac{3}{4}$ of the material needs to be organic (Soil Survey Staff, 1999).

Table 1 Criteria used for classification of organic soils in World Reference Base (IUSS Working Group WRB, 2015) and Soil Taxonomy (Soil Survey Staff, 1999).

Order	Principal Qualifiers/Suborder	Criteria
World Reference Base		
Histosols	Muusic/Rockic/Mawic	Organic soils overlying ice/continuous rock/coarse fragments
	Cryic	Presence of permafrost
	Thionic	Presence of sulfuric acid
	Folic	Naturally well-aerated organic soil
	Floatic/Subaquatic/Tidalic	Organic matter floating on water/submerged in lakes/affected by tidal waters
	Fibric/Hemic/Sapric	Degree of decomposition of organic matter
	Leptic	Having continuous rock in the first 100 cm
	Murshic/Drainic	Naturally drained with cracks and blocky structure/artificially drained organic soils
	Ombic/Rheic	Rain-fed/groundwater-fed wet organic soils
	Hyperskeletal/Skeletal	Organic soils with stones in the first 75 cm/100 cm
	Andic	Presence of weathered pyroclastic deposits
	Vitric	Presence of volcanic glass
	Calcic	Having a calcic horizon in the first 100 cm
	Dystric/Eutric	pH in water $<5.5/\geq 5.5$
Soil Taxonomy		
Histosols	Folists	Freely drained organic soils
	Fibrists	Wet organic soil with weakly decomposed organic matter
	Hemists	Wet organic soil with moderately decomposed organic matter
	Sapristis	Wet organic soil with highly decomposed organic matter

Formation of organic soils

Organic soils form under conditions that reduce the decay of organic material. While cold temperatures are the main determinant for folic horizons, water saturation is the key determinant for histic horizons. In principle it is also possible that organic matter accumulates due to dryness (Xeropreservation), but this does not form organic horizons because of insufficient biomass production. Slow rates of decomposition also occur under unfavorable, e.g., acidic soil conditions. The resulting organic layers in, for example, gymnosperm forests are part of Folic Podzols and rarely grow to a thickness that would allow reclassification as Histosols.

Formation of Folic Histosols

Histosols with a folic horizon develop on bedrock or ice in flat areas in high latitudes and on slopes in high mountain regions. The regions are characterized by cold temperatures which inhibit plant growth and decomposition of organic matter. Also, with reduced biological activity, there is little mixing of the soil through bioturbation. The succession sequence is initially colonization by undemanding vegetation such as lichens and mosses on mostly solid bedrock. Then, first grasses, such as *Carex firma*, and herbs, ferns and heathers establish. With increasing thickness of the organic horizon, dwarf mountain pines (*Pinus mugo*) grow (Fig. 2). Their litter decomposes slowly and leads to further growth of the organic horizon and increases the nutrient stock and availability. With increasing thickness and root space, the mountain pine can be replaced by spruce (*Picea* spp.). Their dead wood also plays a role in organic matter accumulation. Above the tree-line and under deciduous forests, the Folic Histosols are often shallower due to the more easily decomposable organic matter. In the tundra, they reach thicknesses of more than 30 cm, while they can be 1 m thick under coniferous forest. Their rate of accumulation and growth are consequently slow, with average growth rates between 0.1 and 0.3 mm per year. However, a large and rapid supply of poorly decomposable litter can also favor faster accumulation.

Formation of peatlands

Under anaerobic conditions, the decomposition of organic material is low because oxygen (O) diffuses 10,000 times more slowly through water than air. Peat accumulates because more biomass is produced than decays. As a result, there is vertical growth of these organic soils through time. Peat can form directly over wet mineral soil or via terrestrialization or paludification. Organic soils

Fig. 2 A conceptual illustration of the main processes in the formation of Histosols. Folic Histosols form through slow decomposition under cold temperatures. Peat soils develop through terrestrialization, which is the development of peat in open water or paludification which is the development of peat over formerly drier mineral soil, e.g., by water table rise through clearcutting. Paludification may also involve other processes causing groundwater level to rise, such as on indurated soil horizons or after melting of permafrost (not illustrated here).

Fig. 3 (A) peat moss *Sphagnum pulchrum* (© Monika Koperski); (B) weakly decomposed *Sphagnum* peat (© Corinna Schulz, Ron Meier-Uhlherr). From (A) Koperski M (2016) In: *Niedersächsisches Ministerium für Umwelt, Energie, Bauen und Klimaschutz, 2016. Programm Niedersächsische Moorlandschaften. Grundlagen, Ziele, Umsetzung.* Hannover; (B) Meier-Uhlherr R, Schulz C, Luthardt V (2015) *Steckbrief Moorsubstrate. 2., unveränd. Aufl.* HNE Eberswalde, Berlin.

formed by terrestrialization develop by the accumulation of peat in open water systems, either at the bottom of lakes from the accumulation of dead plant biomass or in floating mats. Plant debris from lakes, e.g., sedges and reeds, only partly decompose and accumulate in the lake margin area. The lake might gradually fill from the margins with organic matter. When completely filled, the peat can grow upwards, thereby losing contact with the groundwater and forming rain-fed bogs (Fig. 2). Paludification, on the other hand, describes peat accumulation directly over former drier mineral soil where water-saturated conditions occur through changing external factors such as indurated soil layers in Podzols or melting permafrost. Clearcutting of forest can also lead to peat formation because of the considerable reduction in evapotranspiration with the lack of trees, resulting in a rise in water table (Fig. 2). Consequently, peatlands formed by paludification often have woody peat with tree stumps at the bottom, while terrestrialization peatlands show aquatic sediments at the bottom (Rydin and Jeglum, 2006).

Water saturation inhibits the decay of the peat, but aeration at the soil surface accelerates organic matter decomposition, with potential losses of 80–90% of dry mass. This rate of decay depends strongly on the plant genera, for example, *Sphagnum* moss (Fig. 3) is more resistant to decomposition than parts of vascular plants, e.g., *Molinia* species. Consequently, some plant species are more likely to form peat although it can form from almost all plant genera including trees, mosses, heathers, grasses. Northern peat soils are more likely to be formed by mosses, grasses and reeds, whereas roots of trees provide the main materials for forming peat soils in the tropics.

Organic peat soils grow slowly and need hundreds of years to reach a thickness of several dm. The average rate of growth of peat is 1 mm per year, but it can vary from 0.3 to 13 mm a⁻¹, depending on the region. Most organic soils in the northern hemisphere have formed since the end of the last ice age about 11,000 years ago and reach depths of more than 10 m, but many are shallower. Tropical peatlands can reach greater thicknesses with depths exceeding 20 m. It is estimated that peat soils have an average thickness of 1.3–1.4 m worldwide.

Distribution

Organic soils are predominant in the boreal and subarctic regions of the northern hemisphere. They cover vast areas in Russia, Canada, Alaska, Scandinavia, Great Britain, the Baltic countries, Patagonia and the regions of Central Europe influenced by oceanic climates. Histic organic soils also occur on tropical lowlands, especially in Indonesia, Central Africa and the Amazonas region. Overall, around 3/4 of all organic soils are in the boreal and subarctic regions, another 10% in the mild, rainy, oceanic regions of the mid-latitudes and in mountain regions, and 1/6 in the tropics (Fig. 4; Page et al., 2011). Organic soils occur in almost every region, but their inventory is largely incomplete. In particular, the distribution of tropical peatlands and Follic Histosols has not yet been adequately studied. Follic Histosols occur mostly on a small scale and are often close to other Histosols. The extent of Follic Histosols is estimated to be 0.15% of the Earth's land surface; they are mainly in mountainous regions of the temperate zone. In the absence of precise data, it is estimated that organic soils cover between 2.75 and 4.4 million km² (Yu et al., 2010).

Tundra

Organic soils with both follic and histic horizons are abundant in the subarctic climate zone, namely the tundra which is a biome characterized by open landscapes where tree growth is inhibited by low temperatures. It occurs in high latitudes beyond the northern tree line and in Patagonia and the Falkland Islands. The vegetation is composed mainly of mosses, lichens, grasses and

Fig. 4 Global distribution of peatlands (Based on data from the Global Peatland Database/Greifswald Mire Centre (2021)). The distribution of Follic Histosols is not shown due to their small-scale occurrence and the lack of data. Greifswald Mire Centre <https://greifswaldmoor.de/global-peatland-database-en.html>.

shrubs. The tundra is dominated by permafrost which also makes it impossible for trees to grow. Melting of the upper part of the permafrost in the summer months causes waterlogging in the soil above the frozen ground, which can lead to the formation of shallow peatlands. These polar peatlands are characterized by freeze-thaw cycles and thus form patterned ground, such as polygon mires or palsa mires (Fig. 5 (B)). In other parts of the tundra, however, organic soils have formed without water saturation because of the very slow decomposition of organic matter under low temperatures.

Taiga

The taiga is also referred to as boreal forest and covers large areas of the northern hemisphere. It is particularly abundant in Scandinavia, Russia, the Baltic countries, Canada and Alaska. The taiga is also affected by permafrost and freeze-thaw cycles, which form large mire complexes covering vast areas. The proportion of peatlands in the boreal zone is greater than in any other biome on earth, covering 15% of the boreal land area (Xu et al., 2018).

Temperate zone

In the temperate zone, organic soils occur largely as peatlands and form where sufficient precipitation or high groundwater is available. In oceanic regions such as Ireland or Great Britain, peat soils cover entire landscapes, regardless of their relief (Fig. 5 (E)). These 'blanket bogs' are formed by high precipitation throughout the year and the relatively cool temperatures. They are relatively shallow and develop mainly from grasses, dwarf shrubs and mosses.

In temperate, western European regions like north-west Germany, the Netherlands and Denmark, rain-fed bogs were predominant and widely distributed (Fig. 5C). Nowadays, their occurrence is rather fragmentary as many of the bogs have been drained and destroyed over the last century. Many of these bogs developed after the last ice age in natural depressions and dead ice holes through terrestrialization, where bog peat has developed from fen peat and the influence of groundwater. In addition to bogs, fens are widespread; they form mainly on river floodplains (Fig. 5 (D)) and in terrestrialization zones of lakes. Some local fens form near springs. The widest distribution of peatlands in the temperate zone is on the flat areas of northwest Europe and southern Canada, mainly Québec. Peatlands also form in low mountain ranges and occur on slopes as well as on plateaus and in valleys. There is also a wide distribution of peatlands in the foothills of the Alps in the natural depressions formed during the ice ages.

Tropics

Tropical histic organic soils account for about 16% of all organic soils (Page et al., 2011). Most of the tropical peatlands are in South East Asia, namely Indonesia and Malaysia. However, they also occur in Africa and South and Central America, and the area of Amazonian peatlands is estimated to be similar to or even larger than those in Indonesia (Ribeiro et al., 2021). There is still a scarcity of data, however, on tropical peatlands.

The largest areas of peat soils are in coastal lowlands where they are formed mainly by tree remains, such as branches, roots and trunks, and can reach maximum depths of 40 m. Under high temperature and evapotranspiration conditions, the high rainfall leads to sufficient moisture for peat development. Thus, plant productivity is large combined with slow decomposition through

water-saturated soil. Under these conditions, tropical peat swamp forests form (Fig. 5 (F)), which are mainly dome-shaped bogs that rise above the influence of groundwater. Their hydraulic conductivity is higher than in temperate raised bogs, which makes them more vulnerable to drainage because they are likely to collapse after the water is removed.

Mountain regions

Organic soils are also formed in mountain regions at all latitudes, e.g., the Tibetan plateau, the Alps or the Andean highlands. Under cold temperatures but aerobic conditions, Folic Histosols can form and cover slopes (Fig. 5 (A)), protecting them from erosion. Biological activity is decreased by the cold temperatures, and different organic horizons form with more or less easily identifiable boundaries between Oi ('fibric,' organic horizon with a low degree of organic matter decomposition; plant structures are still intact), Oe ('hemic,' organic horizon with a moderate degree of organic matter decomposition; only fragments of plant residues left, basic morphology, however, still intact), and Oa horizon ('sapric,' 'humified' organic matter, with high degree of decomposition, usually

blackish in color, no macroscopic identification of plant structures possible). Once stored on the cold bedrock, radiocarbon ages may easily exceed several hundreds of years. Nevertheless, even after 1500 years Wang et al. (2019), for instance, failed to discover new organic forms of organic P species, thus questioning a significant role of the humification processes but rather supporting the idea of temperature-controlled preservation and slow microbial synthesis contributing to C and P accrual. This accrual was probably supported by the stabilizing effects of bridging calcium (Ca), stemming from calcareous parent materials. The spatial extent of these soils, however, can be small and isolated, e.g., in cracks between rock fragments but they can also cover several hectares.

Increased rainfall in the mountains through orographic precipitation leads to increased water availability, which, combined with the lower temperatures, enables the formation of histic horizons. Peat soils are formed in valleys and on slopes, but also in the headwaters of rivers and as mires around springs. In mountainous regions, these peat soils are often shallow through the low biomass production at high altitudes. Their distribution and condition are as yet incompletely studied because organic soils are often considered to be mineral soils and used as pastures. Furthermore, they are often in remote areas, which hampers their investigation and mapping.

Characteristics and properties

Organic soils have several properties that distinguish them from mineral soils. One of the most striking is their large C reservoir. By definition, they contain more than 12% C but that often exceeds 50%. Their large organic matter content leads to very low bulk densities which range from 0.01 to 0.2 g cm⁻³ (Rezanezhad et al., 2016), but which increase naturally with increasing mineral content, with soil use and drainage and subsequent compaction (Liu et al., 2022).

Folic Histosols

Organic soils with a folic horizon are freely drained but they have high water retention which promotes organic C accrual. Less decomposed organic matter can hold more water due to larger pore space than strongly decomposed organic matter. Consequently, Oa horizons with sapric organic matter have lower water content and water availability is also less because the small pores of highly decomposed organic matter hardly drain at low suction. The Oi horizons with weakly decomposed organic matter, on the other hand, have good water availability for plants and a higher water holding capacity.

Litterfall decomposition is low and consequently, the organic matter has long turnover times. The nutrient availability is generally low. The concentration and availability of phosphorus (P) is small in Folic Histosols and C:P ratios can exceed 1000 in the upper 50 cm. Further, mobile iron (Fe) and manganese (Mn) have small concentrations in folic horizons, compared to adjacent mineral soils. Nitrogen (N) mineralization is rather small with the inhibited microbial activity. Folic Histosols contain on average 1.6% N and have a C:N ratio of 20–40 which decreases with ongoing decomposition (Vaughan and McDaniel, 2009). With enhanced decomposition, the contents of easily decomposable carbohydrates decrease and also those of lignin, fats and waxes.

The pH depends on the plant community and bedrock, but Folic Histosols have a rather low pH because of the input of acidic litter from coniferous plants and heathers with values ranging from 2.9 to 5. The base saturation (BS) of Folic Histosols is generally low, except for Folic Histosols with a high mineral content or aeolian input, or for those overlying calcareous bedrock. The cation exchange capacity (CEC) is on average 100 cmol_c kg⁻¹, while greater decomposition leads to a higher CEC. The anion exchange capacity (AEC) is generally low at 16 cmol_c kg⁻¹. Both, CEC and AEC, increase with increasing C content (Vaughan and McDaniel, 2009; Table 2).

Table 2 Main properties of the three main types of Histosols.

	<i>Folic Histosols</i>	<i>Rheic Histosols</i>	<i>Ombric Histosols</i>
Genesis	Cold temperatures	Water saturation (ground and surface water)	Water saturation (rainwater)
Vegetation	Grasses, mosses, dwarf trees	Sedges, reeds, alder trees	Mosses, heathers
pH	3.5–5	>4	<4
C:N ratio	20–40	10–33	>33
Cation exchange capacity (CEC)	100 cmol _c kg ⁻¹	80–200 cmol _c kg ⁻¹	70–80 cmol _c kg ⁻¹
Trophic conditions	Mesotrophic to oligotrophic	Eutrophic to mesotrophic	Oligotrophic
Nutrient availability	High N stock Low N availability Low P and K stock and availability Low in Fe, Mn	Moderately to well supplied with nutrients and base cations; depending on groundwater composition	High N stock Low N availability Low P and K stock and availability Low in Ca, Cu, Fe, Mn

Peat soils

Fens and bogs have differences in their properties due to their different water sources. Other properties are, however, very similar and apply to both types of peatland, such as their great affinity to take up and hold water. The water content at saturated conditions ranges from 86% to 94% and undecomposed peat can hold up to 20–30 times its own weight of water. The large water contents make them susceptible to instability, low bearing capacity and shear strength. In general, organic soils are soft and highly compressible, with sinking and slip failure resulting from loads (Fig. 8). Drainage is a way to increase the bearing capacity of peat soils, but this also leads to considerable shrinkage of the soil. Depending on the degree of decomposition, histic horizons can shrink 70% or more upon drying and have a high porosity that can cause irreversible physical collapse.

The peat body can be divided into at least two parts, which differ in the degree of decomposition and in the availability of oxygen. The upper part of the peat body, which consists mainly of living plants and is temporarily aerated, is called acrotelm. The catotelm is the lower part of the peat body, which is permanently anaerobic and consists of dead plant material (Clymo, 1984). This concept has been widely accepted, but also criticized for simplifying the hydrological processes. The boundary between the two layers is not sharp but continuous, and the acrotelm may have developed differently, for example, it depends more on vegetation structure and is usually shallower in fens (Morris et al., 2011). However, some general properties of peat bodies can be derived from the degree of decomposition, such as hydraulic conductivity and composition of the organic matter that usually also change with depth.

The upper, weakly decomposed peat has a high fiber content and the pores are large, open and interconnected, leading to a high hydraulic conductivity, low tortuosity and low flow resistance (Fig. 6). These large pores represent the preferential flow path of solutes, water and colloids (Rezanezhad et al., 2010). This weakly decomposed peat is highly compressible and due to its high hydraulic conductivity and large active porosity, it can shrink and swell with drying and wetting, enabling a water table close to the surface that is independent of water availability (Rezanezhad et al., 2016). With ongoing decomposition of the plant debris into smaller fragments, the pore space and proportion of large pores are reduced (Fig. 6). Consequently, the active porosity decreases because the decomposed peat consists mainly of small, partially closed, dead-end pores. These pores have low interconnection, resulting in restricted flow with low velocity, a large tortuosity and low compressibility (Rezanezhad et al., 2016). The hydraulic conductivity accordingly decreases from undecomposed, fibric peat to hemic to amorphous, sapric peat.

Decomposition processes in peat occur mainly in its upper part as the water table fluctuates, leading to partly aerobic conditions. There, the peat is weakly decomposed but still undergoes intense and ongoing transformations. Almost the whole decomposition process takes place in the upper part of the peat body, which leads to the release of humic acids. The organic matter is dominated by labile C compounds and oxygenated functionalities, like carbohydrates. The O-substituted organic matter plays an important role in microbial humification and decomposition. Thus, during decomposition and with depth, the O contents decrease while the H and C contents increase. The contents of easily degradable carbohydrates and carboxyl-C also decrease, whereas the proportion of more stable structures, such as aliphatic-C, aromatic-C and microbial mucilage-C increases with ongoing decomposition. In the lower part, which is almost permanently water-saturated, decomposition is very slow with the absence of oxygen. Because minor

Fig. 6 Visualization of air-filled pores (red) in *Sphagnum* peat from two different depths, taken by X-ray computed tomography. In the upper layer, the pores are interconnected and larger than in the deeper layer. Modified from Rezanezhad F, Quinton WL, Price JS, et al. (2010) Influence of pore size and geometry on peat unsaturated hydraulic conductivity computed from 3D computed tomography image analysis. *Hydrological Processes* 24, 2983–2994. <https://doi.org/10.1002/hyp.7709>.

transformation processes only take place, this part of the peat body is more homogenous and highly decomposed with a higher proportion of aromatic humic materials (Cocozza et al., 2003).

Other peatland properties, however, do not primarily depend on the degree of decomposition but on the source of water. Therefore, properties, such as pH, CEC and nutrient availability, can be distinguished between groundwater-fed fens and rainwater-fed bogs.

Fens (Rheic Histosols)

Fens vary considerably in their characteristics and properties because they are fed by ground and surface water which is influenced by the bedrock and mineral soil with which it has been in contact. Poor and moderately rich fens have pH values between 4 and 6.4, while rich, alkaline fens contain calcium carbonate and have pH values >6.4. The BS and CEC also depend on pH and values increase naturally from poor to rich fens. At lower pH values of 4–6.4, the CEC and BS range from 80 to 120 cmol_c kg⁻¹ and from 35% to 70%, respectively. At pH 7, the CEC reaches 160–200 cmol_c kg⁻¹ and BS is >70% (Table 2). Consequently, alkaline fens have a good supply of cations, especially Ca and magnesium (Mg), whereas poor fens have small concentrations of both cations (Bourbonniere, 2009).

Fens have moderate to good availability of nutrients, such as P, potassium (K) and others. The concentration of K is highly variable depending on the composition of the water. The availability of P depends strongly on pH because it is often bound to Fe at pH <5 and to Ca at pH >6.5 (Bourbonniere, 2009). Yet, Kooijman et al. (2020) showed that Fe-rich fens are also P-rich with a high P-availability, presumably due to weak P sorption to Fe-OM complexes. The Fe-poor fens, however, had small P-contents and low P-availability. In general, fens have greater nutrient availability than bogs because of their connection to groundwater, but it depends on the composition of the groundwater.

Bogs (Ombric Histosols)

The properties of bogs are less variable than those of fens. Bogs are generally acidic with pH values <4 because rain is their sole source of water. *Sphagnum* mosses further acidify their environment as nutrients are taken up by cation exchange and H⁺ ions are released. Their CEC and BS are also lower than in fens with 70–80 cmol_c kg⁻¹ and 5–35%, respectively. Consequently, the concentration and availability of Ca and Mg is low in bogs because the water has not had contact with mineral soil or bedrock (Bourbonniere, 2009; Wang et al., 2015).

Nutrients are generally scarce in bogs. Bogs contain only small amounts of P, which is mainly organically bound, and the concentration of K is similarly low. The C:P and C:K ratios consequently often exceed 1000 in bogs. In the upper peat, the ratios are lower but increase with depth, indicating a fast recycling of P and K at the surface (Wang et al., 2015). Nitrogen contents usually vary between 1% and 2% (Table 2) and in contrast to P, N accumulates in bogs and the C:N ratio decreases with depth. Even though C:N ratios are large, the main limiting nutrient in bogs is frequently P (Wang et al., 2015).

Utilization

The use of organic soils varies mainly with its properties. Follic Histosols may be used for grazing, but in general they are frequently not used, whereas fens and bogs are often used for agriculture and forestry. Worldwide, 75% of all peatlands are still in a pristine condition, but 25% have already been destroyed or degraded anthropogenically with a further 1% degraded annually. Agriculture is responsible for 50% of this degradation and use, while 30% of peatlands have been anthropogenically afforested.

Follic Histosols as well as fens and bogs are commonly used for grazing. Low-density grazing occurs naturally (e.g., by deer) which maintains the natural vegetation, but commercial grazing includes drainage and some fertilization. Consequently, the vegetation changes and organic soils become prone to compaction, erosion and mineralization. The use as pasture is the most common agricultural use of fens and bogs in Europe.

Crop production on fens and bogs requires drainage, fertilization and some liming. In some regions, other techniques are used to make the wet soils suitable for cultivation. In western Germany and the Netherlands, for example, the cultivation of peat soils started in the 16th century and several techniques were used whose remnants can still be found. One practice was to plough up sand from 2 m to 3 m depth to form diagonally layered sand and peat layers, which were partly covered with a mineral layer (Fig. 7 (A)). In Indonesia, for example, the Mega Rice Project turned native peat swamp forests into rice paddies in 1996. The peatlands were drained and deforested on a large scale. Tropical peatlands are now also frequently drained and partly burned for agricultural plantations.

In the tropics and boreal region, fens and bogs are partly naturally forested. In other regions, the temperate raised bogs or blanket bogs are naturally almost treeless. However, many fens and bogs have been artificially afforested, especially in Fennoscandia, Russia and United Kingdom. Afforestation includes drainage, partial ploughing to create a dry environment, and fertilization to overcome the paucity of nutrients.

Other uses are infrastructure, such as streets or wind farms, and peat extraction, each accounting for 10% of the land use. Peat is mainly extracted for horticultural use and fuel. Its extraction mainly occurs on bogs and includes drainage of large peatland areas. Peat is either extracted in dried sods or milled on the surface. The main peat extracting countries are the Baltic countries, Germany and Canada. Peat extraction leaves shallow peat deposits with cropland, grassland, afforestation, abandonment or restoration as common after-uses.

The use of peatlands varies greatly from region to region. In countries and regions with a high population density such as Western Europe, up to 99% of the peatlands have already been degraded, whereas in large parts of Russia or Northern Scandinavia the peatlands are still largely pristine.

Consequences of anthropogenic use

Organic soils naturally have limited capacity for anthropogenic use, due to high acidity, low nutrient availability and low bulk density, and the vulnerability of organic matter to decompose when aerated. Specific measures may be required such as covering or mixing with sand to reduce wind erosion and risks of fire. When drained, peat shrinks and compacts and aerobic conditions promote oxidative decay of the organic material. Consequently, shrinkage, consolidation and mineralization lead to a loss of height of several centimeters per year, which is further enhanced by wind and water erosion, and possibly burning. The rate of subsidence of peat soils is highest in the first year of up to 1 m and remains at 1–2 cm a⁻¹ in temperate climates and at 3–5 cm a⁻¹ in the tropics in subsequent years (Wösten et al., 1997). In England, for example, a drained peat soil subsided 3.9 m in 130 years, while in Malaysia 2.8 m subsided in 28 years (Hutchinson, 1980; Wösten et al., 1997). Consequently, several meters of peat soil can be lost within a few decades and as a consequence of sustained drainage, the bedrock can come to the surface (Fig. 7 (B)).

Subsidence by mineralization and physical compaction poses additional risks for infrastructure. A famous example occurred in 2017 in the Eastern part of Germany, where highways collapsed on subsiding peatlands (Fig. 8).

Changes in water regime are largely irreversible, as the hydraulic and physical properties change. Consolidation after drainage leads to a higher bulk density which affects hydraulic conductivity and also the plant-available water. Liu et al. (2022) showed, that the available water content increases with increasing bulk density up to 0.2 g cm⁻³, but decreases with further increasing bulk density. Very strongly decomposed peat under agricultural use has low available water contents in the upper decimeters. The small, inactive pores and low porosity of drained and degraded peat mean that plant-available water is lower than in near-natural, less decomposed peat and the crops are more susceptible to drought.

Secondary pedogenic processes are initiated by artificial drainage and use which alter the physical properties of peat soils. Decreased water table depths (10–80 cm) lead to aeration of the upper decimeters and consequently, enhanced decomposition. Weather-related swelling and shrinking in combination with the activity of soil organisms such as earthworms form a crumbly peat structure. This process of enhanced decomposition, the activity of earthworms, and swelling and shrinking, resulting in a crumbly structure, are summarized together under the term earthification. Ongoing and deeper drainage (>80 cm) leads to further decomposition of the peat where the crumbly structure of earthified peat disintegrates into a fine, grainy partly powdery mass when dry which is at risk of wind erosion. When wet, the peat has a greasy, muddy consistence. However, it can also be hydrophobic and when wetted, the peat does not swell but floats on the water surface. The so-called moorshyfted peat is dark brown to black and a further development of earthified peat. Both processes only occur through intensive anthropogenic use with deep drainage.

In addition to secondary pedogenic processes, the anthropogenic use of peatlands affects greenhouse gas (GHG) emissions. The total rates of emission depend strongly on the type of peatland use and the trophic conditions. In boreal and temperate zones, afforested peatlands emit between 0.9 and 9.5 t CO₂ ha⁻¹ a⁻¹, whereas croplands emit on average 29.0 t CO₂ ha⁻¹ a⁻¹ (IPCC, 2014).

Fig. 8 The highway was built on peat soils and subsided due to the insufficient load bearing capacity of peat soils (© Alexander Müller). Alexander Müller, <https://www.ostsee-zeitung.de/Vorpommern/Greifswald/A20-Loch-voellig-ungeeignete-Gruendung>

Aerobic decomposition is strongly influenced by temperature, and CO_2 emissions in drained tropical peatlands are generally higher than in boreal and temperate regions. Depending on water table depth, tropical plantations on peat soil lead to emissions of up to $86.0 \text{ t CO}_2 \text{ ha}^{-1} \text{ a}^{-1}$ (Hooijer et al., 2010) and tropical croplands emit between 48.0 and $51.3 \text{ t CO}_2 \text{ ha}^{-1} \text{ a}^{-1}$ (Hooijer et al., 2010; IPCC, 2014).

Carbon dioxide (CO_2) accounts for the largest emissions from drained peatlands, but nitrous oxide (N_2O), dissolved organic carbon (DOC) and methane (CH_4) also play an important role in the GHG inventory. Nitrous oxide emissions in pristine peatlands are negligible unless affected by nitrate inputs from adjacent farmland, but drainage, subsequent oxidation and fertilization increase the microbial activity and thus, nitrification processes. The N_2O emissions in boreal and temperate zones range on average from 0.22 to $13.0 \text{ kg N}_2\text{O-N ha}^{-1} \text{ a}^{-1}$, while they are generally higher from nutrient-rich sites (IPCC, 2014). Data for N_2O emissions in drained tropical peatlands are still scarce, but overall are more variable than in boreal peatlands (IPCC, 2014). Under warmer climates, N_2O emissions are higher, but they also depend strongly on N availability in the soil. In general, N_2O emissions from organic soils can be predicted by the C:N ratio of the topsoil; soils with a low C:N ratio have higher N_2O emissions (Pärn et al., 2018).

Through the ongoing decomposition of organic matter in drained peat soils, DOC is frequently released and transported through drainage ditches. Under use, DOC export is increased on average by 60% and ranges from 20 to $110 \text{ mg DOC L}^{-1}$ (IPCC, 2014), but several studies have reported much higher values (e.g., Frank et al., 2014). Increased microbial activity through aeration and fertilization is a main factor in the large export of DOC. Dissolved organic carbon is the major component of waterborne C loss in peat soils and also an important factor for further CO_2 and CH_4 emissions from drainage ditches. When drained, peat soils emit negligible amounts of CH_4 or even act as small CH_4 sinks through the uptake by plants. Nevertheless, drainage ditches can form new CH_4 hotspots and contribute to the overall GHG balance of drained peatlands (Köhn et al., 2021).

Anthropogenic change through drainage and forest clearance, and prolonged droughts through global warming increase the risk of peat fires, which contribute to the GHG balance. Peatlands are usually naturally protected against fire by their hydrological self-regulation. However, a deeper water table through drainage exposes the dried, easily flammable topsoil to an enhanced risk of fire. Burning peat is characterized by smoldering combustion, a flameless form of combustion that can persist under cold temperatures, high moisture contents and low O_2 concentrations and can continue over several months. In Indonesia, for instance, major peat fires were intensified by land-use changes and drainage of the peatlands. These large peat fires contribute considerably to the GHG balance of peatlands in certain years. However, exact estimates of GHG emissions from burning peat are difficult to determine because of the often unknown depth of the fire.

The data on emissions from Follic Histosols are scarce because these soils tend to occur on a small scale, are often considered as mineral soil and are mainly used as pasture. There are also inaccuracies in their classification due to different classification systems in different countries. However, Eickenscheidt et al. (2015) showed that the emission factors from C-rich soils can be attributed to land-use type rather than C content, indicating that degradation and use of Follic Histosols can lead to similarly large emissions as the anthropogenic use of peatlands.

Restoration and sustainable use of organic soils

To prevent organic matter losses, related nutrient release and GHG emissions, organic soils should be preserved in their pristine state. This is often no longer possible, therefore the rewetting of degraded peatland sites is recommended (Günther et al., 2020; IPCC, 2014). Rewetting by drain-blocking can restore a high water table and the peatlands' typical vegetation. Some peatlands have undergone partly irreversible changes due to degradation, e.g., in their bulk density, nutrient status and C stability, which still differ from natural peatlands after decades of rewetting (Kreyling et al., 2021; Schimmel et al., 2021).

With rewetting, however, rates of decomposition slow down, promptly reducing CO₂ and N₂O emissions, and DOC loss through drainage waters (Wilson et al., 2016). The direct reduction in GHGs through rewetting ranges between 8 t CO₂-eq ha⁻¹ a⁻¹ in nutrient-poor forestry and 26 t CO₂-eq ha⁻¹ a⁻¹ on former cropland (Wilson et al., 2016). After several years of rewetting, organic matter may re-accumulate, leading to a net C sequestration of 0.12 (±0.40) t C ha⁻¹ a⁻¹, which depends strongly on site and climatic conditions. Boreal peatlands have the greatest potential for C sequestration with rewetting (IPCC, 2014; Wilson et al., 2016). The rewetting of peatlands is an important measure in GHG reduction even if CH₄ emissions increase (Günther et al., 2020).

Rewetting and subsequent anaerobic conditions, nevertheless, favor methanogenesis and CH₄ emissions can increase up to 40-fold (mean: 8.0 ± 10.5; IPCC, 2014; Wilson et al., 2016). There are methods to reduce CH₄ emissions from rewetted sites. First, the water table should be raised gradually and stepwise to avoid inundation in order to reduce CH₄ emissions. Second, the removal of drained and fertilized topsoil prior to rewetting reduces CH₄ emissions by a factor of 30–400 because these are mainly caused by large nutrient concentrations in the peat and decaying labile plant material (Huth et al., 2020).

To rewet peatlands, former drainage ditches need to be refilled. Material is needed for this and if this comes from the soil surface CH₄ emissions are concentrated in a smaller area and reduced overall; peatland restoration goes hand in hand with climate change mitigation. Topsoil removal also reduces the eutrophication of adjacent freshwater and marine ecosystems (Zak et al., 2018). With P mobilization and denitrification of nitrates on rewetting, the large nutrient load in surrounding waters can be an unwanted side effect of peatland restoration (van de Riet et al., 2013). The extent of P release depends on the degree of peat decomposition and redox potential: the more decomposed is the peat by drainage and use, the higher is the P concentration in the upper peat. With rewetting and subsequent decline in redox potential within a few days, P is mobilized from Fe(III)-oxyhydroxides. Even ammonium shows higher rates of release in highly than in weakly decomposed peat (van de Riet et al., 2013). Even though it seems counterintuitive, the removal of fertile topsoil can help in protecting adjacent water bodies from N and P loads, which is also positive for peatland restoration (Zak et al., 2018).

Many sites that have been used conventionally do not meet the objectives of nature conservation, which primarily aims to preserve near-natural peatlands. These peatlands can still be used economically, but with a peat-conserving and sustainable form of land use that can be achieved by paludiculture. Paludiculture is a responsible management option that allows biomass cultivation in wet conditions on rewetted fen and bog soils. As for rewetted peatlands, the high water contents promote C sequestration and reduce GHG emissions (Günther et al., 2020). Depending on the site conditions, different plants are grown on the rewetted sites. The cultivation of reeds, cattail, sedges and reed canary grass is possible on fens (Fig. 9). Rewetted fen soils can also be used as grazing land for, e.g., water buffalo. In formerly drained swamp forests, alder swamp forests can be established through rewetting,

Wichtmann W, Holsten T, Nordt A, Dahms T, Schröder C (2014) Think rural! Think paludicultural! In: Dünkel F, Herbst M and Schlegel T (eds.), *Think Rural!* Springer Fachmedien Wiesbaden: Wiesbaden, pp. 215–231. doi: 10.1007/978-3-658-03931-8_19.

with subsequent use of the wood. On bog soils, peat mosses can be grown on former extraction sites; *Sphagnum* mosses are the main peat-forming plants in raised bogs when the water table is high enough and can serve as a peat substitute and growing medium for other plants.

Outlook

Organic soils cover only minor areas of the land's surface but play a major role in nature conservation and climate change mitigation. So far, there has been insufficient research on organic soils, especially on Follic Histosols and tropical peatlands, whose distribution, depth, condition and properties are largely unknown. With the valuable functions of organic soils for C and water storage and unique habitat for rare species, more research is needed on sustainable restoration and management options. The large C storage potential and emissions from organic soils indicate an urgent need for rewetting to reduce global greenhouse gas emissions.

Abstract

This chapter describes how the interaction between the soil forming factors of climate, relief, organisms, and parent material type results in the formation of anaerobic soil layers due to periodic and sustained waterlogging. The interaction is complex but results in three types of waterlogging regime with differing gley morphology: groundwater encroachment into the soil profile; impedance of downward percolating soil water by slowly permeable soil layers and or substrates; superficial saturation, either by large amounts of rainfall in cold, upland areas, or the deliberate, annual flooding of fields for example, during rice cultivation. The morphology of each regime is described and the way this is used in soil classification at the global level summarized.

Key points

- Most anaerobic soils are the result of permanent or periodic/seasonal water saturated soil conditions.
- For anaerobic conditions to develop fully requires at least about 30 consecutive days of saturation in temperate climates but can require fewer days at saturation in tropical areas.
- Interaction between soil forming factors of climate, relief, organisms and parent material give rise to three different types of waterlogging regime.
- The three types of waterlogging regime are associated with different types of gley morphology and soil profile horizon sequences.
- Gley morphology is some combination of greyish, ferruginous, black, greenish or bluish colors resulting from differences in the color and mobility of iron and manganese under aerobic (oxidized) and anaerobic (reduced) conditions.
- Specific differences in patterns of gley morphology identify the processes that result in soil waterlogging.
- The differences can be used in soil classification to differentiate soil types according to the specific soil waterlogging regime responsible for anaerobic conditions.

*Retired.

Introduction

What do we mean by the Pedology of Anaerobic soils? Pedology is the study of pedogenesis—how soils develop their inherent characteristics driven by environmental weathering processes determined by the dynamic interaction between the variables of climate, organisms and relief acting on parent material over time (Jenny, 1941). In the late 19th Century, the Russian geographer Vasily Dokuchaev, was the first to postulate that soils were natural bodies developed in response to various environmental factors acting at the Earth's surface. He recognized that specific types of soil with a similar sequence of horizontally aligned layers, or soil horizons, occur in areas with distinct types of climate and 'climax' vegetation, such as the Eurasian Steppe and Boreal Forests. This became known as the 'Zonal Soil' concept but it soon became clear that these zones were not as well expressed in the southern hemisphere, or in maritime and equatorial zones where the soil pattern appeared more irregular. It was therefore expanded to include 'Intrazonal' and 'Azonal' Soils which are found in areas where factors other than climate and the climax vegetation, have an overriding influence on the soil characteristics. Anaerobic soils are Azonal and this chapter focuses on describing those factors that result in the formation of anaerobic soil layers, the distinctive types of soil morphology associated with them and their global classification and distribution.

Soil forming factors resulting in anaerobic horizons

Anaerobic conditions in soil develop where oxygen becomes depleted, usually because oxygen uptake by soil biota is not replenished quickly enough by atmospheric diffusion into, or through, the soil profile. This is mainly caused by soil waterlogging but can also be the result of human agricultural mis-practices such as compaction by heavy farm machinery, particularly at times when the soil is wet (the issue of compaction is covered elsewhere in the Encyclopedia), and the unjudicial application of organic manure slurries or ammoniacal fertilizers as well as spillages of petroleum hydrocarbons. The latter four causes can be corrected and will not be discussed further. An excess of rainfall over evapotranspiration means that excess precipitation must be redistributed through the soil profile if waterlogging is to be avoided. This is an important soil function governed by the local interaction between climate, relief, and type of parent material. A final factor, organisms in the form of humans, also creates soil waterlogging through deliberate annual flooding of fields during paddy cultivation.

Climate

Whenever there is an excess of rainfall over evapotranspiration there is the potential for soil waterlogging, however briefly that may last. For the development of anaerobic conditions in soil layers however, waterlogging must be long enough to saturate significant parts of the soil matrix, as well as much of the larger, drainable macropore space, for soil biota to sufficiently deplete the zone of oxygen. The timing for this clearly depends on factors such as biological activity, rates of oxygen diffusion and soil drainage. Studies of soils with morphology associated with anaerobic soil conditions suggest that it is likely to require about 30 consecutive days of waterlogging in most years in temperate zones (Hollis, 1989) and somewhat less than this in tropical zones. Climates with the potential for anaerobic conditions to develop must therefore have, on average, at least 20–30 consecutive days in which rainfall exceeds evapotranspiration. Seasonality is another climatic factor to consider. Tropical climates with warm temperatures all year round are likely to have consistently high rates of evapotranspiration. Therefore, rainfall must be greater than evapotranspiration for prolonged periods for significant waterlogging to occur. In contrast, climates at increasingly high latitudes, both north and south of the equator, will have increasingly longer periods where evapotranspiration is seasonally low so that rainfall during these times is more likely to produce excess water within the soil. In summary, the number of consecutive days when rainfall exceeds evapotranspiration and there is no significant soil moisture deficit (termed the 'field capacity period'), is an important determinant for the likely development of anaerobic soil conditions and the resulting land use.

Fig. 1 shows the distribution of the USDA NRCS soil moisture regimes used in their Soil Taxonomy (Soil Survey Staff, 2014). The classes are based on the average annual duration when the soil, within defined limits, is dry, rather than moist or wet. The exact definitions are complicated and combine the seasonality of rainfall and evapotranspiration with soil temperature, but, for simplicity, those areas with Ustic, Udic and Perudic water regimes have climates in which the soil is moist (or wet) in some part for at least 180 cumulative days or at least 90 consecutive days (45 days where the annual soil temperatures are low). The change from Ustic to Udic to Perudic is based on increasing duration of moist (or wet) conditions, with Udic regimes occurring in humid climates with well distributed rainfall and Perudic regimes occurring where rainfall exceeds evapotranspiration in all months of normal years. Soils with these moisture regimes are not necessarily waterlogged for significant periods but do indicate areas where anaerobic conditions could occur. Aridic and Xeric moisture regimes are restricted to areas unlikely to contain soil with anaerobic layers resulting from climatic factors.

Relief

Once rainfall exceeds transpiration, then the excess water must be redistributed through the soil or over its surface. Slope is clearly an important relief factor here as steeper slopes remove excess water more quickly by surface runoff and lateral flow through upper soil

Fig. 1 Global distribution of USDA Soil Taxonomy Soil Moisture Regimes. Courtesy US Department of Agriculture, Natural Resources Conservation Service, Soil Survey Division, World Soil Resources.

horizons. Topography is the other main factor. Footslopes and low-lying ground such as local hollows and basins, especially where enclosed, are likely to receive more excess water via runoff and drainage than slopes, plateaux, and interfluvies. Anaerobic soils are thus more likely to be found on concave footslopes and low-lying, level ground. Nevertheless, on slowly permeable parent materials (see below), level plateau areas may also become seasonally waterlogged and anaerobic, whilst slope angle will influence the duration and depth at which anaerobic conditions develop (Fig. 2).

Type of parent material

Permeability of the soil and its parent material is the final factor determining the likely development of long-term anaerobic soil conditions. Hollis (1989) reviewed various systems for classifying saturated soil hydraulic conductivity and found that most recognized one or more slow categories with conductivities of $<10 \text{ cm day}^{-1}$. Avery (1980) used this value to define the upper limit of a 'slowly permeable layer' that impedes the downward percolation of excess soil water. Soil and substrate layers with saturated hydraulic conductivities of between 10 and about 100 cm day^{-1} are moderately permeable and likely to conduct excess water sufficiently rapidly to avoid significant waterlogging, particularly in climatically drier areas. More permeable soil and substrate layers with saturated hydraulic conductivity $>100 \text{ cm day}^{-1}$ should be permeable enough to allow infiltration of excess soil water without causing any saturation, unless they are waterlogged by rising water from local groundwater bodies or have underlying, less permeable layers.

Synthesis of the key factors for anaerobic soil development

The local interaction between the three main variables of climate, relief and parent material is complex but results in three broad types of soil waterlogging regime (Fig. 3): groundwater encroaching into the soil profile, impedance of downward percolating soil water by slowly permeable soil layers and/or substrates, and superficial saturation either by large amounts of rainfall in cold upland areas or the deliberate annual flooding of fields, for example, during rice paddy cultivation. These two latter conditions both lead to the development of organic-rich topsoils that retain large amounts of water and release it only slowly so that the upper soil layers remain wet and mostly anaerobic.

As with most things related to soil, there are intergrades between all three regimes. However, by looking at trends in each of the three controlling factors, it is possible to illustrate the likelihood of anaerobic conditions developing for each waterlogging regime (Fig. 4).

Fig. 2 Influence of relief on the distribution of anaerobic soils with permeable and slowly permeable types of parent material.

Fig. 3 Three different types of soil water logging regime resulting in anaerobic soil conditions.

Morphology of anaerobic soils

Mineral soil horizons that experience anaerobic conditions for a significant period in most years develop a distinctive color morphology. This is normally termed 'gley morphology' a term derived from the Ukrainian word 'glei' meaning clay, and used to describe a particular type of wet sticky bluish grey clay. At its simplest, gley morphology comprises a variegated appearance of obviously contrasting grey, ferruginous (rusty) and black colors as shown in Fig. 5. Such distinct mottling is caused by the different ionic forms taken by iron and manganese under periodic aerobic (oxidized) and anaerobic (reduced) conditions. In their reduced form, iron (Fe^{2+}) and manganese (Mn^{2+}) become soluble in water and thus mobile in the soil solution. In this form, they are attracted to negatively charged clay particles in the soil matrix, becoming concentrated in specific areas. When these parts of the matrix become re-aerated, the ions take on their oxidized Fe^{3+} and Mn^{4+} forms, precipitating out as iron oxide and manganese oxide segregations, the pre-cursors of the former often being ferrihydrite. In contrast, those areas of the soil matrix from which the reduced Fe and Mn ions have migrated, are depleted of these elements, and take on a pale greyish color. The gleying process is facilitated by the ability of some microbes to survive anaerobic soil conditions by developing metabolic pathways of respiration using compounds other than oxygen, including transition metals such as Fe^{3+} and Mn^{4+} (Lecomte et al., 2018). This ability initiates the reduction of iron and manganese in waterlogged soil layers. These anaerobic soil processes are explained in more detail elsewhere in the Encyclopedia.

Fig. 4 Relationship between soil waterlogging regimes and trends in excess rain, parent material permeability and relief.

Fig. 5 Common gley morphology resulting from alternating periods of anaerobic and aerobic soil conditions. Courtesy Centre for Environmental and Agricultural Informatics, Cranfield University, College Road, Cranfield, United Kingdom.

Development of this basic gley morphology clearly depends on the weathering of iron compounds in the soil and thus the mineralogy of the soil parent material. Hematite forms of iron are particularly stable and resistant to reduction. Consequently, gley morphology is weakly expressed in soils formed on reddish parent materials characterized by this type of mineralogy (Thomasson and Robson, 1967). Similarly, soils formed in sedimentary parent materials that have small contents of ‘free’ iron (extractable by sodium dithionite) have small amounts of ‘reduceable’ iron (Van Bodegom et al., 2003) and weakly expressed gley morphology. In both cases, the color contrast between parent material colors and any oxidized ferruginous segregations or iron-depleted zones is muted, even where anaerobic conditions are prolonged.

Reduced conditions are effectively permanent where a soil layer never dries out enough to allow air into the soil matrix and, in mineral soils, this is usually indicated by the presence of predominantly greenish grey, greyish green or bluish grey colors indicating the presence of iron in its reduced form, and few, if any, ferruginous mottles (Fig. 6).

This is the basic gley morphology of mineral anaerobic soils, but the exact patterns and relationship of the contrasting colors, both within the matrix and down the soil profile, depend on the different processes of saturation. Such differences are important as they enable us to infer the cause of waterlogging that results in anaerobic conditions within the soil profile.

Table 1 Horizon Nomenclature used in this chapter.

<i>Master Horizons</i>	<i>Description</i>	<i>Same as Soil Taxonomy?</i>
A	A mineral horizon formed at the surface.	Yes
B	Subsoil mineral layers in which pedogenetic processes have obliterated any original sedimentary bedding or rock structure.	Yes
C	Layers, excluding hard rock that show little effect of pedogenetic processes.	Yes
E	Subsoil layers in which eluvial processes have resulted in the loss of silicate clay, iron, aluminium, or some combination of these.	Yes
H	An organic layer saturated, or formerly saturated with water for prolonged periods	No
W	A waterlogged soil layer	Yes
Suffixes to Master Horizons	Description	Same as Soil Taxonomy?
a	An Organic horizon with highly decomposed organic matter	Yes
d	A dense soil layer that restricts roots	Yes
e	An Organic horizon with intermediate decomposition of organic matter	Yes
g	A mineral horizon with gley morphology indicative of waterlogging resulting from a slowly permeable layer	No
h	A mineral soil layer with accumulation of organic matter	No
i	An Organic horizon with little decomposition and many recognizable fibrous plant remains	Yes
l	A mineral horizon with gley morphology characteristic of the capillary fringe above a (W) groundwater table	No
m	An horizon that is cemented by pedogenetic processes	Yes
o	A mineral horizon with residual accumulation of sesquioxides, including ferruginous segregations	Yes
p	A surface cultivated layer	Yes
r	A dark greyish, bluish or bluish-green soil layer indicating strong reduction and the presence of iron in its reduced state	No
s	A mineral soil layer with illuvial accumulation of sesquioxides	Yes
w	Used with a mineral B horizon to indicate the development of color and/or structure but no pedogenetic features	Yes
x	A compact subsoil horizon with Fragipan characteristics of firmness, brittleness and often platy structure with high bulk density	Yes

Modified from Chapter 5 and Table 85 of FAO (2006) Guidelines for Soil Description. 4th edn. Food and Agriculture Organization of the United Nations: Rome.

The ultimate expression of anaerobic soil conditions is the development and accumulation of superficial, black, or dark reddish brown organic material called peat. This situation occurs where almost continuous anaerobic conditions, often exacerbated by acid or cold conditions, inhibit the biological breakdown of superficial dead vegetative material which starts to accumulate. Where these conditions persist over centuries, peat layers can extend to a thickness of many meters. Different peat horizons within the soil profile can be distinguished by the extent to which their plant remains have been broken down into amorphous organic matter, a process known as humification and, where identifiable, their main constituent plant species.

To differentiate specific types of morphology in individual soil horizons, it is convenient to use a shorthand nomenclature. Whilst a number of these types of nomenclature have been developed, the one used here is that of the Food and Agriculture Organization of the United Nations (FAO, 2006). Most of its notations are similar to those used in the USDA Soil Taxonomy (Soil Survey Staff, 2014) and its Field Handbook for describing and sampling soils (Schoeneberger, et al., 2012). The nomenclature is an alpha-numeric one in which capital letters designate so-called 'Master' horizons or layers, lower case letter suffixes identify specific characteristics of the master horizons, and numbers placed either before or after the letters indicating, respectively, either a lithological change from the overlying horizon, or a sequence of successive horizons with the identical nomenclature. Table 1 summarizes the nomenclature as it applies to anaerobic conditions.

The following sections summarize the specific controlling factors and associated morphology of each of the three waterlogging regimes illustrated in Fig. 3.

Anaerobic soil resulting from saturation by a rising local water table

There are three main situations where a rising water table results in temporally fluctuating anaerobic conditions in the local soil cover. Each situation has soils with different morphology and horizon sequence.

Local and regional groundwater bodies

Groundwater bodies form in geological strata where rainfall infiltrates through the surface layers to a depth where it is unaffected by evaporation or extraction forces exerted by transpiring vegetation. It then continues to percolate through any underlying permeable sediments until it reaches an impermeable layer such as massive clay or hard dense rock where it starts to back up, gradually filling the air spaces in the strata through which it has travelled. Depending on the local topography and the seasonal balance between

rainfall and evapotranspiration, the resulting saturated groundwater body rises near to the land surface creating streams, rivers and wetlands in the lowest parts of the landscape. Such surface water features are often initiated as springs. Significant groundwater bodies only form in relatively permeable material and their upper levels depend on the balance between rainfall and evapotranspiration. When rainfall exceeds evapotranspiration for a significant time, recharge of the water body occurs and its upper surface rises. When the reverse is the case, its upper surface falls. In higher latitudes, both north and south of the equator, the groundwater surface tends to fall during late spring, summer, and early autumn, whereas in tropical latitudes the surface will rise during the rainy season and fall during the dry season.

During the year therefore, there are two zones associated with groundwater bodies, an upper zone that experiences alternating periods of anaerobicity and aeration, and a lower zone that is permanently saturated and anaerobic. Finally, because of surface tension forces in the porous medium of the groundwater body its upper surface is overlain by a thin, superficial capillary zone in which the pores are partially saturated, the extent of saturation decreasing upwards. How far these zones affect the soil profile depends on local topography as illustrated in Fig. 2.

Mineral soils in which full or periodic groundwater saturation rises to immediately below the topsoil can be recognized from their distinctive sequence of soil horizons (see Fig. 7). Under natural or semi-natural vegetation, there is a superficial A or H horizon (see Table 1), usually with a moder or mor humus form (Zanella et al., 2011), depending on the average duration of saturation, or, if farmed and artificially drained, an A horizon with mull humus form. The immediately underlying subsoil is either a Bo horizon showing the mottled grey and ferruginous colors indicating periodic reduction, segregation and re-oxidation of iron resulting from a fluctuating groundwater table, or an E horizon in which periodic saturation and reduction of iron are followed by removal of the reduced iron by leaching, either laterally or vertically. At the base is a BCl or Cl horizon with a mottling pattern characteristic of the capillary zone. Ferruginous iron oxide segregations are concentrated on ped and pore surfaces or around root fibers, indicating those preferential pathways by which air enters the horizon as it de-saturates. In contrast, capillary surface tension means the finer pores remain saturated so that the bulk of the soil remains greyish and anaerobic. This mottled zone passes down into a wet, predominantly greyish, or bluish colored Cr horizon which in its upper parts may also show thin, ferruginous iron oxide segregations lining pores or root fibers.

Anaerobic peat soils that develop because of saturation by a rising local water table are usually restricted to discrete enclosed hollows in the landscape which may contain open water. Here, the vegetation fringing waterbodies comprises water tolerant reed (*Phragmites*), rush (*Juncaceae*) and sedge (*Cyperaceae*) species, the remains of which constitute the main plant remains although woody fragments of trees such as willow (*Salix alba* L.) and alder (*Alnus glutinosa*) may also be present. As the water body fills with sediment and the vegetation spreads, peat accumulates, and occasionally obliterates the open water area. Once the accumulated

Fig. 7 Gley morphology associated with the capillary zone of two soils under different land use, affected by a rising groundwater table. Courtesy Centre for Environmental and Agricultural Informatics, Cranfield University, Cranfield, United Kingdom; <http://www.flickr.com/photos/fortgirl/sets/72157617791529911/detail/> (CC BY-NC-SA 2.0)2.

peat rises above the level of ground waterlogging, then intermittent aeration affects the highest parts, accelerating peat humification to an extent where a balance between accumulation and humification is reached and peat growth ceases. Where rainfall is large enough, a final phase of peat accumulation occurs. At this stage the saturated upper layers are maintained solely by rainfall and the vegetation starts to be dominated by wet-tolerant species such as *Sphagnum* moss, 'cotton grass' (*Eriophorum* species) and tussock grass (*Poa flabellata*). Continued rainfall-generated growth of peat layers dominated by these plants enables the peat layers to rise above those maintained solely by groundwater saturation and this type of climax lowland peat is known as a 'raised bog', characterized by acid conditions deficient in nutrients, especially nitrogen and phosphorus.

Tidal saltmarshes and mangrove swamps

Coastal fringe areas where low-lying land is saturated by the rising tide have a specialized vegetation and a distinctive soil biomass adapted to the daily inundations. It usually includes marginal marine crustaceans. The inundation cycle means that, although upper horizons are exposed to the atmosphere for some hours, they do not usually become fully aerated, remaining wet but not saturated. The resulting soil profile has a semi terrestrial hydric, organic (H), or organo-mineral (Ah) humus form, the latter usually being massive with very little, if any, structural development because of its permanent wetness. Horizon development below this is indistinct, with a dark, organic (He), or dark greyish to bluish organo-mineral BC, C or Cl horizon with muted dark reddish-brown areas that may represent ferrihydrite formed during the short period of daily exposure to air. Lower parts are effectively an 'unripened' W layer comprising loose sediments that are permanently waterlogged with very low bearing strength (Fig. 8). If the land is reclaimed by isolation from the tidal cycle and installation of land drainage, these layers start to dry out, irreversibly losing some water, becoming more consolidated and starting to develop the classic gley morphology associated with profiles affected by seasonally fluctuating groundwater.

Seepage

Local seepage areas, often termed 'flush' sites, occur on mid- to foot-slopes where there is a significant reduction in the permeability between overlying porous strata and underlying impervious strata. Water bodies that build up over the junction with less pervious material seep out at the surface, causing prolonged periods of saturation following rainfall. Such sites are usually localized and easily identified by the distinctive presence of species tolerant of wet conditions (Fig. 9).

The soil morphology of these sites is conditioned by the extent and duration of local waterlogging, as determined by the rainfall frequency or seasonality, and the relief around the seepage site. Anaerobic soils will only develop at seepage sites that are waterlogged regularly enough to ensure the development of their characteristic vegetation. Those where rainfall is seasonal or infrequent are likely to become aerated for significant periods, at least in their upper parts. Here the upper subsoil horizons usually exhibit the grey and ferruginous mottling characteristic of Bo horizons affected by a fluctuating groundwater table. Similarly, if the local slopes around the site enable some surface run off and or lateral drainage to remove excess water gradually, then the profile again exhibits Bo subsoil horizons. In contrast, where rainfall is more frequent and or local relief is subdued, then saturated conditions persist for much of the time and a slightly different profile morphology develops (see Fig. 9). In cold, acid, usually upland areas that receive large amounts of rainfall, a peaty, semi-fibrous He topsoil horizon with a mor humus form develops. Where slopes allow at least some lateral seepage through the upper layers, the peat is underlain by a predominantly greyish subsoil E horizon, almost completely depleted of iron. This is because leachate from the peat topsoil is acid and contains soluble organic compounds that form complexes with any reduced iron in the horizon, which is then removed during continuous lateral flow. Below this wet grey horizon is a permanently waterlogged Cr horizon where seepage, whether lateral or sub-vertical, is not sufficiently rapid to remove its excess water. Here, greyish colors predominate with a few areas of darker reddish brown iron segregation, possibly composed of ferrihydrite.

Anaerobic soils resulting from superficial saturation

The development of anaerobic conditions caused by superficial saturation within a soil profile depends on the dynamics between excess water input, the saturated vertical and lateral hydraulic conductivity of layers within the soil profile or its immediate substrate and the amount of any downslope surface run-off. Where rainfall frequency and magnitude are such that the rate of excess water moving into the soil exceeds the saturated hydraulic conductivity of any soil or substrate layer, then waterlogging is likely to occur. If this situation continues for a significant period, anaerobic conditions will develop, their duration and vertical extent within the soil profile depending on the duration of saturation. All soils subject to this type of waterlogging regime have a distinct gley morphology in that there is a greater degree of gleying in their upper portions, in contrast to the morphology associated with waterlogging by rising local water tables.

Again, there are three main situations that give rise to this type of waterlogging regime.

Superficial saturation resulting from impeded vertical drainage

As described in the section on soil parent material, soil horizons or substrates with a saturated lateral hydraulic conductivity of less than about 10 cm day^{-1} , are likely to impede the downward percolation of excess water, causing it to accumulate and saturate the impeding layer and, normally, the overlying material. Such impeding horizons are dense and either massive, or with coarse prismatic or blocky peds and less than about 50% total porosity, the latter having a distinctly bi-modal size distribution. A small proportion only of the total porosity comprises coarse pores large enough to allow excess water to drain vertically (at least

approximately 0.06 mm average diameter), and these pore sizes usually represent 5% or less of the total volume of the soil layer (Fig. 10). In addition, very small pores which hold water so strongly that plants are unable to extract it, usually comprise at least half of the total porosity.

The characteristics of these slowly permeable horizons give rise to a distinctive gley morphology. As excess water moves into the horizon, the air spaces in the small fraction of coarse pores, the junctions between soil peds and the root channels become saturated relatively quickly. From these areas, soil water diffuses very slowly into the ped matrices. The saturated, coarse pore network quickly becomes anaerobic, reducing any iron on the mineral interfaces. This reduced iron, now mobilized, is either removed by vertical or lateral flow, or diffuses into the ped. Once within the ped, the reduced iron is preferentially attracted to, and retained by, negatively charged clay particles. In this way, the edges of peds, pores and root channels become depleted of iron whilst, within the ped, iron becomes segregated. Once the horizon starts to dry out and aerate, then the iron-depleted ped and pore faces remain grey and the ped interiors take on the characteristic variegated grey and ferruginous segregation resulting from alternating periods of anaerobic and aerobic conditions (Fig. 11). This type of gley morphology is denoted in horizon nomenclature by a g suffix.

Such gley morphology is the basic characteristic of mineral soil profiles with anaerobic conditions resulting from impeded vertical drainage, but there are two distinct soil horizon sequences that can be recognized depending on the duration of saturation

A broken very coarse prismatic ped taken from a slowly permeable horizon about 12 hours after significant rain.

that occurs within about 50 cm of the soil surface. Profiles which are saturated within this depth for significant periods have an organo-mineral Ah, or occasionally an organic semi-fibrous He, topsoil horizon, below which is the variegated grey and ferruginous mottled Bo horizon common to many anaerobic soils (Fig. 12, profile a). Where the horizon is more permeable, or the profile is on a significant slope, then there is no Bo horizon and, instead, a wet, iron-depleted E horizon is usually present (Fig. 12 profile b). In either case, these horizons overlie the defining slowly permeable Bg horizon. In contrast to anaerobic soils resulting from a rising groundwater table, the gley morphology of the Bg horizon becomes less well defined with depth, gradually merging into what

Source	Value	Standard error	t	Pr > t	Lower bound (95%)	Upper bound (95%)

Fig. 13 Relationship between field capacity days, depth to slowly permeable layer and duration of soil waterlogging within 40 cm depth.

appears to be a less saturated BC(g) horizon in which structure is often defined by a few grey colored semi-vertical fissures and a matrix that has lost less of its inherent color but has patches of ferruginous iron oxide segregations and fewer greyish colors. Eventually, where deep enough from the surface to be unaffected by weathering processes, the unaltered C horizon is reached. Alternatively, profiles in which there is no prolonged saturation within 50-cm depth have a modified horizon sequence in which the two upper horizons are a mineral Ah horizon over a relatively well-aerated Bw horizon showing little, if any, gley morphology merging downwards into a lower sequence showing some combination of Bo, Bg, BC(g) and C horizons formed below 50 cm depth (Fig. 13 profile c).

The extent to which the upper parts of the soil profile become anaerobic depends on the depth at which the slowly permeable layer occurs, the duration of field capacity and the magnitude of excess rain during this period, although these latter two are usually strongly positively correlated. The data described by Hollis (1989) include measurements of the duration of waterlogging within both 70-cm and 40-cm depths for up to 3 years at a large number of sites across England and Wales. The two recording depths were chosen because they are used in the definitions of soil wetness classes for England and Wales (Hodgson, 1997) and indicated how soils functioned with respect to crop growth. At each site, duration of the field capacity period for each year was recorded, as well as the depth to the slowly permeable layer. These data have been analyzed by stepwise linear regression to examine the influence of the independent variables of field capacity days (FCD) and depth to slowly permeable layer (DSPL) on the duration of waterlogging within 40-cm depth for soils that exhibited gley morphology starting within 100-cm depth. The analysis showed that both FCD and DSPL were highly significant explanatory variables and that the derived regression equation had an adjusted R^2 value of 0.853 (Fig. 13). With this relationship, it is possible to plot the combinations of FCD and DSPL that would give a duration of waterlogging of 30 days which is the probable minimum required to result in the gley morphology associated with anaerobic soil conditions in temperate zones (Fig. 13). This suggests that, for those soils with a slowly permeable layer starting at shallow depth (20–30 cm), anaerobic conditions would be present within 40-cm depth in areas with as few as 60–70 field capacity days. For soils in which a slowly permeable layer did not start until deep in the profile (80–90 cm), anaerobic conditions would only encroach within 40-cm depth in areas with 160–180 days at field capacity.

Superficial saturation resulting from excessive rainfall

In climates where rainfall frequency and magnitude exceed the ability of even moderately permeable superficial soil horizons to transmit the excess water either vertically or laterally, then they tend to become partially or completely waterlogged. Where this situation extends for prolonged periods, anaerobic conditions will develop. Such situations are particularly prevalent in uplands where cold, wet, and acid conditions inhibit the breakdown of superficial organic material, and an organic-rich or a peaty topsoil develops. On the wettest upland plateau areas and basins, peaty H horizons dominated by plant species tolerant of waterlogged conditions, can accumulate to the extent that thick peat soils blanket the landscape.

Where rainfall is slightly less, or the land slopes more, then, even though the largely anaerobic, water-retentive peaty topsoil is present, it overlies mineral subsoil horizons into which its excess water is continually seeping. The uppermost mineral subsoil

horizons are thus variably saturated and only periodically aerated. The distinguishing characteristic of this type of soil is a change from anaerobic conditions (with large reducing capacity) in upper horizons to aerobic conditions (with large oxidizing capacity) in lower horizons.

The wet, acid nature of these types of anaerobic soils means that they often develop spodic horizons in the upper parts of their well-aerated subsoil zone. Such profiles have a typical horizon sequence with a peaty H topsoil of variable thickness and a mor humus form, overlying a greyish, acid Eo horizon with a few ferruginous segregations formed during short periods of aeration. In places this horizon is abruptly terminated by a thin, irregular, dark reddish brown to black cemented Bsm 'iron pan', the lateral coherence of which can be variable, and elsewhere there is a more gradual transition to a spodic Bs or a non-podzolic Bw horizon (Fig. 14). These horizons merge downwards into the relatively unaltered C horizon, usually through a transitional BC.

Superficial saturation resulting from paddy cultivation

Soils under rice paddy field cultivation probably constitute one of the most extensive types of anaerobic soils in the world. They are subject to a specific anthropic type of waterlogging regime resulting from the deliberate creation of a compacted lower topsoil that is intended to prevent downward percolation of surface water channeled into fields by a system of peripheral ditches and small sluice gates (Fig. 15). Their gley morphology and full horizon sequence takes time to develop following the initiation of paddy cultivation; the exact period varies with the local soil textural and structural characteristics. In many cases it is likely to be more than 100 years (Kögel-Knabner et al., 2010). The characteristic features of the profile comprise three horizons developed by the annual paddy creation process. The first two of these are the result of cultivation when the field surface is partially wet. This creates a compacted 'plough pan' at the base and a superficial wet 'puddled layer'. The latter is a dark-colored, often organic-rich Ap horizon that, when not flooded, has a loose consistence with assorted small-sized peds. Underlying this is the compacted Ad plough pan horizon that impedes downward percolation when the overlying topsoil is waterlogged. It has a massive or platy structure, with a matrix usually showing the paler colors created by prolonged reduced conditions. If ferruginous segregations are present, they occur mainly around root channels or coating any structural fissures. These two layers overlie a structured Bg horizon of variable thickness, depending on the permeability of the soil parent material. Its gley morphology is similar to that of subsoil horizons in soils with superficial saturation resulting from impeded vertical drainage. It is characterized by peds with greyish iron depleted faces and an internal matrix dominated by ferruginous segregations but with greyish-colored pore surfaces often spreading a few millimeters inwards. Where the soil parent material is permeable, the Bg horizon merges downwards into an aerobic BC or C horizon; the change from anaerobic to aerobic conditions is similar to that of soils where superficial saturation results from excessive rainfall. In contrast, profiles with less permeable substrates, show a gradual downwards change from the Bg horizon to a BC horizon in which the greyish and ferruginous colors become less pronounced and the inherent color of the parent material dominates.

Artificial field drainage

An additional anthropogenic soil forming factor affecting anaerobic soils is the installation of field drainage systems designed to ameliorate waterlogged conditions quickly in the upper parts of the soil to facilitate crop growth. The successful installation of such systems enhances drainage from waterlogged upper layers, aerating them or, at the least, significantly reducing the duration of anaerobic conditions. The installation and management of these artificial drainage systems has been the subject of a considerable amount of research and is covered elsewhere in the Encyclopedia.

In many areas where anaerobic soils result from superficial saturation by excess rainfall, productive agriculture is precluded because of climatic conditions, making the cost of effective artificial drainage uneconomic. Elsewhere, anaerobic soils resulting from rising ground water tables require different types of drainage systems from those resulting from impeded vertical drainage. Where effective, the installation of field drainage increases the aeration of upper soil horizons that were formerly either permanently anaerobic, or experienced alternating anaerobic and aerobic conditions. This is likely to increase microbial activity resulting in increased organic carbon turnover and loss of carbon from upper horizons. Former moder or mor humus forms will change to mull forms, especially if the drainage is accompanied by cultivation. However, subsoil gley morphology is unlikely to change significantly in Eo or Bg and BCg horizons because any ferruginous segregations are already in their oxidized form and grey areas are already depleted of iron. Only where soil bioturbation by faunal or vegetative activity is intense enough to mix the different components of these horizons gradually, will gley morphology be lost, starting from the base of the topsoil. Because the reason for installing effective field drainage is to enable more intensive agricultural or forest production, such bioturbation is unlikely to be intense enough to change the morphology significantly. This means that some gley morphology may be a relic feature and not representative of the current soil water regime, but resulting either from recent agricultural drainage, or previous climatic conditions.

Where permanently saturated horizons extended to at least the base of the topsoil, then if field drainage is effective, and the upper horizons become aerated, the characteristic gley morphology is likely to change. Air initially infiltrates into the horizons by pore networks and root channels resulting in oxidation of the reduced iron on their surfaces forming a network of ferruginous segregations; the same as that of the capillary fringe horizon associated with fluctuating groundwater tables. Eventually, as air infiltrates into the soil, structural formation and brunification of the horizon will begin. The rapidity with which this process happens depends on the effectiveness of the drainage and the length of time it persists.

Classification of anaerobic soils

Anaerobic soils are recognized in most national systems of soil classification but, understandably, the terminology used, and level of importance attached to them varies depending on the environmental characteristics of each country. At the global level however, there are two principal classification systems that can be applied: The USDA NRCS Soil Taxonomy (Soil Survey Staff, 2014) and the FAO/IUSS World Reference Base (WRB) for soil resources (IUSS Working Group WRB, 2015). Both systems are hierarchical and have evolved through several iterations as understanding of the Pedosphere, its soil forming processes and their controlling factors increased. Both also define soil types by the presence or absence of diagnostic characteristics that may be horizons, properties, or materials. This concept was introduced in the first iteration of Soil Taxonomy and was an important advance, enabling scientists to identify soil horizons with properties of sufficient importance to influence soil behavior. The classification of anaerobic soils with the types of waterlogging regime defined above are set out in Table 2.

United States Department of Agriculture (USDA) soil taxonomy

The USDA Soil Taxonomy system has five hierarchical levels: Orders; Suborders; Great Groups; Subgroups; Families. At the highest level, there are 12 Orders defined by the presence of important characteristics that are diagnostic of important soil processes. Each Order is increasingly subdivided at each level depending on the presence of other specific diagnostic characteristics. The names of different soil types at different levels are a combination of part of the Soil Order name and prefixes based on the names of specific diagnostic characteristics. Soil profiles with significant periods of anaerobic conditions caused by waterlogging are defined as having an Aquic moisture regime, and Aquic conditions are a diagnostic property used at the Suborder, Great Group and Subgroup levels, depending on the depth at which saturation starts within the soil profile and the type of saturation present. Three types of Aquic Conditions are defined:

- Endosaturation, where the profile is saturated to at least 200-cm depth in all layers from the upper boundary of saturation.
- Episaturation, where the soil is saturated in one or more layers within 200-cm depth, but also has at least one layer below the saturated layer that is unsaturated within 200 cm.
- Anthric saturation, where the profile has a tilled surface layer, an underlying slowly permeable layer and a subsurface horizon with a gley morphology indicative of alternating periods of anaerobic and aerobic conditions (greyish areas and areas of ferruginous segregations).

Table 2 Classification of Anaerobic soils.

Waterlogging Regime	Upper level (cm)	World Reference Base		Soil Taxonomy			
		1 ^a	2 ^a	1 ^a	2 ^a	3 ^a	4 ^a
Saturation by a rising local or regional water table or a seepage site	Base of topsoil or within 40 cm	Gleysols Histosols	Rheic	–	Endoaqu-	–	–
	<75	–	Gleyic	–	–	–	Aquertic Aquic -Aqu- Oxyaquic
	76–100	–	–	–	–	–	–
Diurnal saturation by tidal regimes	Base of topsoil or within 40 cm	Gleysols or Solonchaks	Tidalic	Entisols	Endoaqu-	–	–
Superficial saturation resulting from impeded vertical drainage	Base of topsoil	Planosols Stagnosols Solonetz Vertisols	Stagnic Stagnic	–	Epiaqu-	–	–
	<75	–	Stagnic	–	–	–	Aquertic Aquic -Aqu- Oxyaquic
	76–100	–	–	–	–	–	–
Superficial saturation resulting from excessive rainfall	Soil surface	Stagnosols ^b Podzols	Histic Umbric Stagnic ^b Histic	–	Epiaqu-	–	–
Superficial saturation resulting from Paddy cultivation	Soil surface	–	Hydragric Anthraquic	–	Epiaqu-	–	–

^aThese numbers denote the hierarchical level at which the specified diagnostic characteristics are applied within each classification system. The symbol – in a column means that it applies to more than one class within the specified level.

^bThe Stagnic properties that are diagnostic for this waterlogging regime do not have the gley morphology related to slowly permeable horizons (greyish colors dominant on structure and pore faces) but still qualify as Stagnic through the criteria 1a, 2 or 3.

Organic (peat) soils of the Histosol Order that have Aquic conditions for at least 30 days during normal years are subdivided at the Suborder level into Fibrists, Hemists, or Sapristis depending on the extent of humification in the profile, with Fibrists being least humified and Sapristis most humified.

Mineral soils with anaerobic conditions are distinguished at the Suborder level using the term Aqu-, denoting the presence of an Aquic moisture regime, added to a component of the Order name. Thus, in the Order of Alfisols, Suborders with an Aquic moisture regime are termed Aqualfs, and within this Suborder, the terms Epiaqualfs and Endoaqualfs are used to characterize Great Groups with Episaturation and Endosaturation, respectively. Although the diagnostic condition of Anthric saturation is recognized, it doesn't appear to be used, at least in the top five hierarchical levels. This means that, at present, it must be included with one of the other two Aquic Conditions, probably that of Episaturation.

In Soil Taxonomy therefore, mineral anaerobic soils resulting from a rising local water table would be classed as Endoaqu -, whereas those resulting from superficial saturation would be classed as Epiaqu -, the - indicating a combination of letters derived from the Order within which the soil profile has been classified.

Food and Agriculture Organization (FAO)/International Union of Soil Science (IUSS) World Reference Base

The FAO/IUSS WRB system has only two hierarchical levels: a set of 32 reference soil groups (RSGs) that represent the major soil types of the World and approximate to the zonal soil concept; a second level which identifies additional specific characteristics of each RSG using 'qualifying' terms, which can be considered as adjectives that describe the presence of important diagnostic characteristics in addition to those used to characterize the RSG.

Peat soils developed because of prolonged waterlogging and associated anaerobic conditions are included in the Histosol reference soil group and qualified as either Ombric Histosols, where saturation is the result of excessive rainfall, or Rheic Histosols, where it is the result of rising local water tables. Paddy soils showing a full expression of anaerobic conditions in terms of the upper puddled and plough pan layers, recognized as a diagnostic Anthraquic horizon overlying a greyish and ferruginous mottled diagnostic Hydragric horizon are classified as Hydragric Anthrosols.

Mineral soils subject to anaerobic conditions within 50-cm depth are recognized within three other reference soil groups:

The Gleysol reference group is characterized by gleyic properties resulting from saturation by a local rising groundwater table. Specific differences in gley morphology that reflect differences in the intensity of reductive saturated conditions are used to qualify the group as follows: Reductigleyic Gleysols are those that do not have any significant ferruginous segregations (mottles) within

40-cm of the soil surface, whilst Oxygleyic Gleysols do not have any layers that lack significant ferruginous segregations within 100-cm of the soil surface. In addition, soils in saltmarsh areas that are inundated to near the surface at high tide are differentiated as Tidalic Gleysols.

The Planosol and Stagnosol reference groups are recognized by the presence of diagnostic stagnic properties exhibiting the characteristic gley morphology of slowly permeable horizons. The former reference group is differentiated by an abrupt change in clay content between coarser textured upper horizons and finer textured underlying horizons, but their diagnostic gley morphology is similar and no further qualifiers related to differences in anaerobic patterns are made.

Those soils where anaerobic conditions occur only lower in the profile and do not affect the upper soil horizons where the bulk of vegetative roots occur, are recognized using qualifying adjectives in soil classes other than those mentioned above. Two main terms are used. Gleyic reference group qualifiers are applied where Gleyic properties diagnostic of saturation by a rising local water table, are present within 75-cm but not to the base of the topsoil. Stagnic reference group qualifiers are applied where stagnic properties diagnostic of saturation caused by slowly permeable horizons are present within 75-cm, but not to the base of the topsoil.

Finally, in situations where the degree of waterlogging that resulted in anaerobic gley morphology has significantly reduced, but the morphology remains unchanged, especially where effective field drainage has been installed, two qualifying terms are used. Relictigleyic or Relictistagnic are used with reference groups other than Gleysols, Planosols or Stagnosols, to indicate the presence of gleyic or stagnic property morphology within 75-cm depth but no reducing conditions. In Gleysols, Planosols and Stagnosols with an artificial field drainage system that may have effectively aerated the upper soil horizons but where reducing conditions still occur within 75-cm depth, the Drainic qualifier is used.

Geography of anaerobic soils

Anaerobic soils are globally widespread but in geographically distinct areas. There are no current maps at the global level that adequately show the different types of waterlogging regimes, but the following gives an overview of their geography:

- Most anaerobic soils that have developed because of saturation by a rising local water table occur in and fringing the river floodplains of continental drainage basins and in coastal saltmarsh and mangrove swamps.
- A few are found in small local lower- and foot-slope seepage areas or confined hollows in flatter areas, both where permeable strata overlie impermeable strata. These areas rarely cover more than a few tens of square meters, but can occur anywhere with a suitable combination of relief and geological conditions and sufficient rainfall to generate regular groundwater recharge.
- Those anaerobic soils that have superficial saturation caused by excessive rainfall are mainly confined to upland plateau, brows, and upper slopes, and or areas where rainfall exceeds evapotranspiration for much of the year.
- Anaerobic paddy soils occur mainly in the monsoon areas of southeast Asia where 90% of the world's rice is grown (Dong and Xiao, 2016, Fig. 4). More restricted areas are globally diverse, occurring in parts of California and southeast USA, central America and the Caribbean, Peru, Chile, Brazil, Uruguay, Spain, Italy, west Africa, Madagascar and southeast Australia.
- Anaerobic soils that have superficial saturation cause by impeded vertical drainage in slowly permeable material are not well mapped at the global scale, mainly because their distinctive gley morphology has only recently been acknowledged in many countries. They occur wherever climates have an excess of rainfall over evapotranspiration for significant periods of the year and slowly permeable material such as weakly consolidated massive clay or glacial till, within about 200-cm depth. The Soil Atlas of the Northern Circumpolar Region (Jones et al., 2009) shows that Stagnosols are scattered within a relatively narrow zone extending from Ireland in the west into central Asia in the east, corresponding mainly to the Udic and to a lesser extent the Ustic moisture regime areas (see Fig. 1). It is likely that these types of soils, including Planosols will also occur in all areas with similar soil moisture regimes, where slowly permeable parent materials occur.

Conclusions

The impact of soil anaerobic conditions affects both the composition of the soil biological population and the ionic forms of some common soil elements, particularly iron and manganese. Most anaerobic soil conditions are the result of waterlogging in soil layers and the duration and frequency of such waterlogging results in a distinctive 'gley morphology' of variegated greyish, ferruginous, and black (manganiferous) colors that is easily recognized in a soil profile. However, few soils remain permanently waterlogged to the surface, most experiencing alternating periods of anaerobic 'reducing' conditions and more aerated 'oxidizing' conditions. Only those soil horizons that remain permanently saturated have consistently greyish, dark bluish or bluish green colors with no ferruginous areas. The different ways that soil waterlogging develops, whether from rising groundwater levels or surface saturation, determine how the soil matrix and its pore spaces wet up and re-aerate. These different waterlogging regimes produce distinct differences between the exact location of greyish, ferruginous, and black areas and this enables us to infer the type of waterlogging regime causing the anaerobic conditions. Such differences can be utilized in soil classification to inform us of soil pedogenesis at any site. They can also enable us to devise the best way to ameliorate anaerobic conditions that inhibit plant growth, through specific types of field drainage, or, if wetland restoration is the desired aim, what level of management is needed to increase its likely success.

Abstract

Alluvial soils, formed in alluvium deposited by streams and rivers, are useful and productive soil resources. Alluvium has varied particle-size distributions and occurs in all climates. It underlies geomorphic surfaces ranging in age from the present day to millions of years. As a consequence of the range of conditions for their formation, alluvial soils are extremely diverse. They are important for understanding landscape evolution, and for flood control and food security.

Key points

- Alluvium and alluvial soils are very diverse, with properties depending on the ultimate rock type source, climate, and geomorphic surface age.
- Alluvial soils occur on alluvial fans and terraces, and floodplains.
- Alluvial soils are important for understanding landscape evolution and soil formation, for flood control, and for the production of food and fiber.
- The loss of prime agricultural land from urbanization and industrialization is a serious threat to food security.

Introduction

Alluvial soils are some of the world's most useful and productive soil resources. Alluvium, the parent material of alluvial soils, is the sediment deposited by fluvial systems such as rivers and streams. Alluvium includes a wide variety of mineralogical compositions and particle-size distributions, depending on the source of geologic materials and depositional environment. Alluvium occurs in all climates and underlies geomorphic surfaces ranging in age from present day to millions of years. Therefore, alluvial soils that have formed in alluvium are extremely diverse. Alluvial soils are also important for use by humans such as for understanding landscape evolution, flood control, and food security.

Alluvium

Alluvium is ultimately derived from the weathering and erosion of igneous, sedimentary, and or metamorphic rocks, such as basalt, limestone, or gneiss, respectively. Alluvium may also be derived from the erosion of other unconsolidated sedimentary deposits, including colluvium (gravity-deposited), lacustrine (lake-deposited), loess or eolian sand (wind-deposited), or older alluvium, that has been deposited in a fluvial system. Important characteristics of alluvium, which ultimately influence the properties of alluvial soils, include chemical and mineralogical composition and particle-size distribution. The type of landform composed of alluvium and the stability and age of its surface (geomorphic surface) also influence soil formation and use and management by humans.

Mineralogical composition

The mineralogical composition of alluvium depends on the lithology, or type of rock material, from which the sediments are ultimately derived. Alluvium derived from sedimentary rocks such as limestone and dolomite will be calcareous (contain calcite, CaCO_3). Alluvium derived from gypsum-bearing shale will be gypsiferous (contain gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$). Alluvium derived from igneous rocks lacks carbonates and gypsum. Alluvium from mafic igneous rocks, such as basalt and gabbro, will be rich in magnesium- and iron-bearing silicate minerals, whereas alluvium from siliceous igneous rocks, such as rhyolite and granite, will be rich in quartz and silica-rich feldspars. Alluvium derived from mixed lithology will have mixed mineralogy. The north-south trending San Joaquin Valley of central California, USA, for example, has alluvium derived from the granitic rocks of the Sierra Nevada mountain range on the east side and alluvium derived from the marine sedimentary rocks of the Coastal Ranges on the west side. Alluvium in the east is dominated by silicate minerals including quartz and silica-rich feldspar with minor amounts of biotite and hornblende. In contrast, alluvium in the west contains varying amounts of carbonate, sulfate, and silicate minerals, reflecting the shale, siltstone, sandstone, and limestone sedimentary rocks of the Coastal Ranges.

Particle-size distribution

The particle-size distribution of alluvium depends primarily on the energy of the fluvial environment in which sediments are deposited. High-energy fluvial systems, such as channels of braided streams, can carry and ultimately deposit relatively large (coarse) particles. Glacial outwash, a type of alluvium deposited by high-discharge glacial meltwater streams, typically has a large volume of rock fragments (gravel and cobbles) and sand. Low-energy fluvial environments transport and deposit smaller (finer) particles. As water rises in a stream and overflows its banks, coarser particles are deposited adjacent to the channel, eventually building up natural levees, and finer particles are deposited by the overbank flood waters. Overbank flood deposits often exhibit a fining of upward particle-size distribution as coarser particles (sands) settle faster from suspension than finer particles (silt and clay). An example of gravely channel deposits and silty overbank flood and distal fan deposits is shown in Fig. 1.

Alluvium is generally considered to be well sorted—each layer of the alluvial deposit exhibiting a relatively narrow range of particle-size distribution. However, different components of the stream channel vary in water flow velocity, which affects the erosion, transport, and deposition of sediment. Stream channels can migrate across the landscape in response to changes in water discharge and bed loads. Therefore, alluvium can be stratified, i.e., composed of alternating layers with different particle-size ranges (e.g., Fig. 2). The stratigraphy, or study of the relative positions, of alluvial deposits can provide clues to the history of landscape evolution.

The lithology and physical weathering characteristics of the source of alluvium also influence the particle-size distribution. Alluvium derived from sandstone is typically sandy, as the cement between sand grains is weathered and the sand grains are eroded, transported and deposited in fluvial systems. Alluvium derived from granitic rocks is typically sandy to fine gravely—the size range of the individual mineral grains—because the granitic rock fabric typically shatters into individual grains upon weathering. Alluvium derived from finer textured rocks and sediments is finer textured. For example, alluvium derived from the erosion of fine-textured lacustrine sediment typically lacks rock fragments and is rich in silt and clay.

Fig. 1 Schematic representation of the Holocene Green Canyon alluvial fan cut into and deposited on lacustrine deposits of Pleistocene Lake Bonneville, Cache Valley, northern Utah, USA. Streams draining rocky limestone and dolomite uplands (R) deposited gravely channel alluvium (Gr) and silty overbank and distal fan alluvium (Si). These Holocene soils are the Green Canyon series (loamy-skeletal Typic Haploxerolls) formed in gravely alluvium, and the Millville series (coarse-silty Typic Haploxerolls) formed in silty alluvium. (Information derived from the Soil Survey of Cache Valley Area, Utah).

Fig. 2 Holocene alluvial soil in the arid climate of the Circle Cliffs area of the Colorado Plateau, Garfield County, southern Utah, USA, showing stratification typical of alluvium. This soil is mapped as the **Radnik** series (coarse-loamy Ustic Torrifluvents), and the profile is about 1.2 m thick.

Landforms

Alluvium occurs in deposits that comprise a variety of different landforms, such as alluvial fans, alluvial terraces, alluvial plains, floodplains, and footslopes or toeslopes where hillslopes transition into alluvial fans. Pleistocene glacial outwash occurs on outwash terraces.

Streams draining mountainous terrain that discharge into wide valleys or basins deposit sediments as fan-shaped landforms termed alluvial fans (Fig. 3a). Alluvial fans are common in low-lying areas adjacent to tectonically active mountain ranges, including those in western North America, Central America, and South America; central Asia; southern Europe; the Middle East, and eastern and southern Africa. Components of alluvial fans include channels, floodplains, fan terraces, and dissected fan remnants. Alluvial fans emanating from adjacent streams can coalesce and form bajadas (Fig. 3b). Finer textured distal fan deposits can form alluvial plains or alluvial basins on the valley floor. Overbank flood deposits can form inter-fan basins between low-gradient alluvial fans. Alluvial fans generally slope away from the sediment source, with steeper slope gradients occurring higher and gentler slope gradients occurring lower on the fan.

Fig. 3 (A) Alluvial fan emanating from a stream; (B) Alluvial fans coalescing to form a bajada; west side of the Wah Wah Mountains of the Basin and Range, Millard County, western Utah, USA. Photos courtesy of Eugene W. Schupp, Utah State University.

Fig. 4 Photograph of head-trained Zinfandel wine grape vineyard on alluvial terraces on the west side of Dry Creek Valley, Sonoma County, California, USA. Reddish surface soil (*Manzanita* series, fine-loamy Ultic Palexeralfs) is mapped on the gently sloping higher terrace in the foreground formed in the oldest alluvium, intermediate aged soil (*Yolo* series, fine-silty Mollic Xerofluvents) is mapped in the middle ground on a lower nearly level alluvial terrace, and the youngest soil (*Cortina* series, loamy-skeletal Typic Xerofluvent) is mapped on the lowest floodplain adjacent to Dry Creek (marked by trees). Cobb Mountain is the peak visible in the center background.

Floodplains and alluvial terraces occur parallel to the stream or river, as illustrated in Dry Creek Valley of northern California (Fig. 4), and by the extensively studied alluvial terrace system developed parallel to the Guadalquivir River, southern Spain (Calero et al., 2008, 2009). Recent alluvium occurs on almost level floodplains and recent alluvial terraces adjacent to streams and rivers. Older alluvium occurs on alluvial terraces, also known as stream terraces or river terraces, that are generally higher than the associated floodplains and are not subject to frequent flooding. Higher terraces can be subject to upland erosion and dissection as the valley is incised by the river, as demonstrated in the Tagus and Duero river valleys of central Spain (Roquero et al., 2015).

Alluvial soils

The morphological, physical, chemical, and mineralogical properties of alluvial soils depend greatly on the characteristics of the alluvium (parent material) in which the soils formed, especially when the soils are young. As alluvial soils develop over time, the other soil-forming factors (climate, organisms/biota, and relief) influence the resulting soil properties. As alluvium is often well sorted, the particle-size distribution and stratification of layers influence the movement of water and air through the soil.

Recent alluvial soils

Soils on active floodplains receive deposits of new alluvium with each flooding episode. The amount of alluvium deposited during each event will vary. Small amounts of material deposited on the soil surface can be barely perceptible and sediments can be incorporated rapidly into the underlying surface horizon, the rate of which depends on climate and biota. Plants adapted to frequently flooded soils may survive and grow up through the newly deposited sediment, with soil fauna facilitating mixing of the newer sediments into the soil. Larger amounts of alluvium deposited in thicker layers may completely bury underlying soils, setting soil-forming time back and resetting the geomorphic surface age to zero. If there is sufficient time between flooding events for the geomorphic surface to stabilize, plants to establish, and soil organic matter to accumulate, A and/or O horizons may develop.

Recent alluvial soils affected by periodic flooding and sediment typically have somewhat elevated concentrations of organic carbon at depth. New alluvium is often derived from the eroded A or O horizons of upland and/or upstream soils. If the deposit of

Fig. 5 Photograph of a fine-textured alluvial soil with a buried A horizon on a recent (Holocene) alluvial terrace of the Little Bear River, Cache County, Utah, USA. The alluvium was derived from the erosion of older sediments deposited by Pleistocene pluvial Lake Bonneville. The soil profile is about 1.4 m thick.

new alluvium is significant, landform stabilization and soil formation can result in a soil with one or more buried A and/or O horizons. (Fig. 5). Thus, soils with buried A and or O horizons demonstrate an irregular decrease in organic carbon with increasing depth.

Climate and biota further influence the properties of recent alluvial soils. The soils in humid climates generally support dense vegetation, thus developing A and or O horizons more rapidly than in drier climates. Highly soluble minerals such as gypsum and salts more soluble than gypsum (halite, NaCl; soda, Na_2CO_3 , etc.) present in the parent alluvium, will be rapidly dissolved and leached in humid climates, whereas these constituents are often retained (and can accumulate) in arid and semiarid climates.

Older alluvial soils

In general, older alluvial soils develop when they are no longer subject to periodic events that involve flooding and sediment deposition. Geomorphic surfaces and landforms are more stable and thus able to support a mature vegetation cover. Organic carbon in the subsoil eventually decomposes and the soil develops a regular distribution of organic carbon with increasing depth.

Climate, which influences vegetation and associated biota, further modifies the properties of alluvial soils. In cold climates with permafrost, cryoturbation (mixing of soil by freeze–thaw) can disrupt stratification of alluvial layers. In warmer climates, the available precipitation influences the resulting soil properties because water is required for soil-forming processes such as chemical weathering of minerals, decomposition of organic matter, translocation of clay, leaching of soluble constituents, oxidation and reduction of iron, etc. In humid climates, older alluvial soils are commonly leached of carbonates and other more soluble minerals, and resulting in a low base saturation. With time, B horizons develop in the subsoil and accumulate constituents such as silicate clay, free iron oxides, and or metal–humus complexes. Soils on different-aged alluvial terraces illustrate how alluvial soils develop over time. In Mediterranean-type climates soils typically increase in clay content, have redder Munsell color hue (e.g., Calero et al., 2008), decrease in pH and carbonates, and increase in iron and aluminum oxides with increasing age (e.g., Calero et al., 2009; Martín-García et al., 2016). Similar trends are observed in humid temperate climates, including changes in soil properties associated with decreasing inherent fertility, such as decreasing cation exchange capacity and decreasing extractable micronutrients with increasing age (Shaw et al., 2003). In subhumid, semiarid, and arid climates, alluvial soils may be incompletely leached and B horizons commonly accumulate carbonates (e.g., Sion et al., 2022) and or silica (e.g., Kendrick and Graham, 2004). In more arid climates, gypsum, and or salts more soluble than gypsum can accumulate, depending on mineralogy of the alluvium and the landscape setting (e.g., Moghiseh and Heidari, 2012).

Older alluvial soils have often been subject to changes in climate during their development. This is particularly the case in soils formed in alluvial valleys or basins over hundreds of thousands to millions of years, such as the valleys and basins of the Basin and Range physiographic province of western North America. Very old alluvial soils can exhibit the imprinting of several climate regimes, e.g., well developed, clay-rich B horizons that have been engulfed by calcium carbonate accumulations such that clay skins (clay films, argillans) are no longer visible in the soil morphology observed in the field, but are evident in the soil micromorphology observed with a petrographic or electron microscope.

Alluvium, alluvial landforms, and the associated alluvial soils can be subject to active fluvial processes at one time or another. Therefore, all or a portion of an alluvial soil may be eroded and new sediment can be deposited adjacent to and or overlying the

older alluvial soil (e.g., Gile and Hawley, 1966; Eghbal and Southard, 1993). There may be erosion only of the upper soil horizons overlying a B horizon that is relatively resistant to erosion, such as a carbonate-rich and or clay-rich B horizon. Such a truncated soil may have the B horizon exposed at the soil surface. Recent alluvial deposits may bury a truncated soil. As the deposit and the geomorphic surface stabilize and soil development occurs, soil-forming processes alter the recent overlying alluvium. If the recent alluvium is thin, soil formation can extend into the older buried alluvial soil, which is sometimes referred to as having a welded profile.

Alluvial soils often retain at least a partial record of the Earth's history through alluvial deposition, landform and geomorphic surface stabilization, soil formation, and subsequent erosion. The stratigraphy of soils across the landscape records the geomorphic and soil-forming processes influenced by the environment. Therefore, alluvial soils in their landscape context are useful for soil-geomorphic studies. The degree of soil development on alluvial surfaces has been used to understand landscape evolution (e.g., Eghbal and Southard, 1993), correlate geomorphic surfaces of similar ages (e.g., Gile and Grossman, 1979; Harden, 1987; Roquero et al., 2015), decipher paleoclimate, and assess the tectonic activity of faults that cut alluvial surfaces. Understanding landscape evolution and the formation of alluvial soils also facilitates the mapping of soils (e.g., Fig. 1).

Classification

Recent alluvial soils that lack significant development of surface or subsurface diagnostic features are classified into the order of Entisols (U.S. Department of Agriculture Soil Taxonomy; Soil Survey Staff, 2014) or reference soil group of Fluvisols (World Reference Base; IUSS Working Group WRB, 2015). In Soil Taxonomy, the formative element 'fluv' indicates the alluvial origin and the stratified nature of recent alluvial soils. Alluvial Entisols little affected by saturation and reducing conditions that have relatively large organic carbon concentrations (greater than or equal to 0.2%) at depth (125 cm) or an irregular decrease in organic carbon with depth (see Fig. 5) classify into the suborder of Fluvents. Fluvents are further subdivided into 'great groups' by soil moisture regimes (e.g., Udifluvents with a udic [humid] soil moisture regime, Torrifluvents with an aridic [arid] soil moisture regime, etc.). Similar Entisols that are saturated for prolonged periods during a normal year classify into the great group of Fluvaquents. Alluvial soils in drier climates may classify in the Entisols suborder of Orthents (e.g., Torriorthents, Xerorthents, Ustorthents, and Udorthents), which vary in soil moisture regime. In the World Reference Base, soils with fluvic material, with evidence of obvious stratification or relatively large organic carbon concentrations (greater than or equal to 0.2%) and an irregular decrease in organic carbon with depth, classify as Fluvisols.

With greater landform stability and soil development, alluvial soils can develop into a myriad of different soil types and be classified into several different orders of Soil Taxonomy and into several reference soil groups of World Reference Base. In Soil Taxonomy, alluvial soils in arid climates that have subsurface diagnostic horizons (e.g., argillic horizon, calcic horizon, gypsic horizons, duripans, petrocalcic horizons, etc.) classify as Aridisols. Alluvial soils with mollic epipedons (thick, dark, soft, A horizons) and high base saturation throughout the soil depth are Mollisols. Other alluvial soils with ochric or umbric epipedons classify as Spodosols, Oxisols, Ultisols, Alfisols, Inceptisols, depending on the diagnostic subsurface horizons and properties present and the degree of leaching indicated by base saturation. Gelisols, Vertisols, and Andisols are also possible, depending on climate and diagnostic horizons and properties. In the World Reference Base, older, more developed, alluvial soils can be classified into more than 20 reference soil groups, depending on their diagnostic horizons, properties, and materials. Examples include Gleysols, Podzols, Ferralsols, Chernozems, Calcisols, Lixisols, Luvisols, and Cambisols. For illustration, the five soils in the Guadalquivir fluvial chronosequence were classified according to the World Reference Base/Soil Taxonomy as Haplic Fluvisol/Typic Xerofluvent (0.3 ka), Haplic Calcisol/Typic Calcixerept (7 ka), Cutanic Luvisol/Haplic Palexeralf (70 ka), Lixic Calcisol/Calcic Haploxeralf (300 ka), and Cutanic Luvisol/Haplic Palexeralf (Calero et al., 2008).

Human uses of alluvial soils

Alluvial soils have been the sites of the earliest agriculture. For millennia, humans have used alluvial soils, especially those that are young and less developed, for the production of food and fiber. New alluvium rich in organic matter and nutrients provide fertile soils for agriculture. Alluvial soils are often deep, occur on nearly level land, and are relatively easy to cultivate. In drier climates, the occurrence of alluvial soils near sources of water for irrigation of crops facilitated the development of agriculture and civil society. For example, early agricultural societies with rich cultures developed along the Tigris and Euphrates rivers in the Middle East, the Nile in Egypt, and the Ebro in the Iberian Peninsula. However, irrigated alluvial soils can be subject to salinization.

Indigenous cultures throughout the world raise crops on alluvial soils, particularly on recent alluvial soils that are productive and easy to cultivate. Periodic flooding results in the rejuvenation of soil fertility by depositing organic-matter-rich sediment and nutrient-rich water on soil surfaces. Zuni and other indigenous peoples of the arid and semiarid southwestern U.S. used the periodic deposition of runoff and sediments eroded from hillslope soils onto traditional agricultural fields on alluvial fans to grow crops and sustain soil quality (Norton et al., 2007).

Recent alluvial soils on floodplains are subject to periodic flooding and urban and industrial development should be avoided. These soils are important for flood control and can provide other ecological benefits. For example, the Yolo Bypass in the Central Valley of California near Sacramento diverts floodwaters away from urban and high-value agricultural land while providing wildlife habitat.

Even today, alluvium and alluvial soils underlie the most productive agricultural regions of the world. For example, the Central Valley of California supports a vibrant, multi-billion-dollar agricultural industry. However, many of the soil and landscape properties that make alluvial soils attractive for agriculture are also attractive for residential, commercial, and industrial development. Alluvial soils are often deep and well-drained; occur in wide, nearly level valleys or plains; and are easy to excavate. Therefore, thousands of hectares of productive agricultural lands on alluvial soils are being lost each year to urbanization and industrialization. Alluvial soils can also provide the gravel and sand for road base and for concrete for construction.

Conclusions and outlook

Alluvium and alluvial soils are important for understanding recent Earth history through landscape evolution and soil formation, for flood control, for construction materials for roads and buildings, and for the production of food and fiber. The loss of prime agricultural land to urbanization and industrialization; the degradation of alluvial soils by erosion and salinization; and the dwindling supply and quality of irrigation water for agriculture in a rapidly warming climate are serious threats to food security on local, regional, and global scales.

Given changes in climate and the importance of these soils to humans, future research on the impacts of climate change on alluvial soils is needed. Because alluvial soils occur on different aged geomorphic surfaces, in different parent materials, and in different climates, further research on properties and genesis could provide insight on potential soil and land use change as climate changes.

Abstract

Hydric soils are found in wetlands. They develop in areas that are saturated and anaerobic for periods long enough for redoximorphic features to form, and/or for organic C to accumulate, all within 30 cm of the soil surface. Hydric soil field indicators are soil layers having well-defined colors, specific quantities of redoximorphic features, and organic C contents, that are used to identify hydric soils in the field. The Hydric Soil Technical Standard describes how a hydric soil without field indicators can be identified using measurements to determine if the soil becomes saturated and anaerobic.

Key points

- Hydric soils form in wetland environments subject to prolonged saturation and anaerobic conditions.
- Hydric soils were defined to enforce wetland protection laws in the United States.
- They are identified using field indicators of hydric soils that document characteristic morphological features.
- The Hydric Soil Technical Standard provides a mechanism to link hydric soil form and function.

Introduction

Hydric soils are those that form in wetlands. The term 'hydric soil' was defined in the United States as part of the national effort to protect wetlands from being destroyed through drainage or the placement of fill materials (Vepraskas, 2016). The concept of hydric soils and the methods used to identify them follow specific requirements in the United States, and these will be summarized in this chapter. How hydric soils are identified in other countries will be illustrated by discussing some of the major soil classification systems that are used around the world.

Hydric soils are defined as "soils that formed under conditions of saturation, flooding, or ponding long enough during the growing season to develop anaerobic conditions in the upper part." (Federal Register, 1994). The 'upper part' is loosely defined to be the soil between depths of 0 to 30 cm in soils with a loamy or clayey texture, and between the depths of 0–15 cm in sands. When organic soil materials are present at the soil surface, the upper part may be only 1 cm thick or less depending on the land region where the soil is found. This is the official definition that was incorporated into a number of federal statutes and as a result it cannot be easily changed. Vepraskas et al. (2016) provides a complete history of the concept and definition of hydric soils.

The term 'hydric soil' was used for the first time in the wetlands classification system of Cowardin et al. (1979) to describe the soils found in frequently saturated or inundated ecosystems. The Cowardin system was used by the United States Fish and Wildlife Service to develop the National Wetlands Inventory (NWI) that mapped wetlands across the United States. It defined wetlands as: "...lands transitional between terrestrial and aquatic systems where the water table is usually at or near the surface or the land is covered by

Table 1 U.S. Government statutes that protect wetlands.

<i>Federal Act</i>	<i>Year Passed</i>	<i>Lands Affected</i>	<i>Federal Agency for Enforcement</i>	<i>Actions Prevented</i>
Clean Water Act	1977	Wetlands on non-agricultural land and forested wetlands on farms	U.S. Army Corps of Engineers and the Environmental Protection Agency	Filling or draining wetlands without a permit
National Food Security Act	1985	Wetlands on agricultural land except those in forests	U.S. Department of Agriculture-Natural Resources Conservation Service	Draining wetlands for agricultural production

shallow water. For purposes of this classification wetlands must have one or more of the following three attributes: (1) at least periodically, the land supports predominantly hydrophytes, (2) the substrate is predominantly hydric soil, and (3) the substrate is non-soil and is saturated with water or covered by shallow water at some time during the growing season of each year."

Hydric soils are now identified primarily to enforce water protection laws in the United States that were enacted through Congressional Acts. The two major acts shown in [Table 1](#) prevent wetlands from being filled in or drained without a permit first being obtained from the federal agency enforcing the laws. These laws required the boundaries of wetlands be identified on maps of individual parcels of property ([Hurt and Noble, 2016](#)). Each wetland is expected to meet separate requirements for wetland hydrology, hydric soils, and hydrophytic vegetation.

Hydric soils in soil classification systems

Hydric soils were defined independently of any scientific soil classification system, but similar soils can be found in most soil classifications containing saturated and chemically-reduced (i.e., anaerobic) soils. For example, in the United States soil classification system *Soil Taxonomy*, mineral soils that are saturated and reduced, either continuously or periodically, have 'aquic conditions' ([Soil Survey Staff, 2014](#)). The presence of aquic conditions can be determined in the field from direct measures of saturation with piezometers or wells, and documenting reducing conditions through either measurements of oxidation-reduction (redox) potentials, use of dipyrindyl dye, or by 'Indicator of Reduction in Soil' (IRIS) tubes (i.e., iron oxide coated pipes, [Berkowitz et al., 2021](#)). However, aquic conditions are more commonly identified using readily observable redoximorphic features characterized by mottled gray or red colors that form in response to prolonged or repeated periods of chemical reduction ([Vepraskas and Vaughan, 2016](#)).

Of the 12 soil orders defined in *Soil Taxonomy*, 10 have suborders that require aquic conditions be present "for some time in normal years" ([Soil Survey Staff, 2014](#)). [Table 2](#) shows that the occurrence of aquic conditions is identified in the taxonomic name at the suborder level when they occur within 50 cm of the soil surface. Aquic conditions are not identified in Aridisols, which are found in deserts, but some soils in this group do saturate periodically and may be hydric soils. Histosols are organic soils that require at least 30 days of saturation in normal years, but do not require the soils to be reduced or anaerobic. In reality, most Histosols probably do develop reducing conditions when saturated at temperatures when microbes are active, and so there is no need to recognize aquic conditions in a separate taxonomic group in Histosols.

All hydric soils have aquic conditions, but not all mineral soils with aquic conditions are hydric soils. [Table 2](#) shows that to be classified as having aquic conditions at the suborder level, a soil must have redoximorphic features (i.e., mottled soil color patterns) within 50 cm of the surface. Hydric soils, on other hand, must have redoximorphic features within 30 cm of the surface for loamy and clayey materials, and within 15 cm of the surface for sandy soils. In addition, the saturated and reduced conditions needed for aquic conditions can occur at any time during the year, while for hydric soils they must occur during the frost-free growing season when microbial activity is occurring in the soil.

The World Reference Base for Soil Resources (WRB) is an international soil classification system that also includes saturated and reduced soils ([IUSS Working Group WRB., 2015](#)). Like *Soil Taxonomy*, it does not recognize hydric soils as a distinct group, but includes such soils in at least four major 'reference soil groups': Gleysols, Histosols, Planosols, and Stagnosols. The characteristics of each of these groups are summarized in [Table 3](#). The reference soil groups are further defined for specific soils using principal and supplemental qualifiers, examples of which are also shown in [Table 3](#). A hydric soil might be classified as a Sapric Histosol (Hyperorganic, Sulfidic) for example.

Examples of soil orders or the highest levels in the classification systems used by Russia, China, Australia and Brazil that contain hydric soils are shown in [Table 4](#). Additional details for the lower categories of these classification systems were summarized by [Buol et al. \(2011\)](#). Because not all systems use the term 'soil order' we will refer to these levels simply as categories. These classification systems were selected to show how terms for the classification categories that contain hydric soil can vary around the world. Hydric soils occur in both mineral and organic soils for each of the classification systems shown in [Table 4](#). As with *Soil Taxonomy* and the WRB systems, organic soils are designated as a separate soil category. Unlike *Soil Taxonomy*, mineral soils that are saturated for long periods, such that they develop low chroma or gleyed colors (redoximorphic features), are separated out into their own categories (e.g., Gley soils).

Table 2 Taxonomic groups from *Soil Taxonomy* which contain hydric soils.

<i>Soil Order</i>	<i>Aquic Suborder</i>	<i>Examples of Aquic Great Groups</i>	<i>Depths of Aquic Conditions or Redoximorphic Features cm</i>	<i>Examples of Soil Series with Hydric Soils^a</i>	<i>General Comments</i>
Alfisols	Aqualf	Glossaqualf Endoaqualf	≤50	Sebring	Soils with accumulation of clay in subsurface, higher base saturation and pH than Ultisols
Andisols	Aquand	Epiaquand Endoaquand	40–50	Onomea	Soils commonly formed in volcanic materials
Aridisols	NA ^b	NA	NA	NA	Desert soils
Entisols	Aquent	Sulfaquent Fluvaquent	≤50	Chincoteague	Young, undeveloped soils
Gelisols	NA	Aquorthel Aquiturbel	≤50	Mankomen	Soils frozen at least part of the year
Histosols	NA	NA	≤40 for some classes	Ponzer	Soils formed from organic materials
Inceptisols	Aquept	Fragiaquept Humaquept	40–50	Chastain	Soils showing more development than Entisols, but less than other soil orders
Mollisols	Aquoll	Argiaquoll Cryaquoll	40–50	Espelie	Soils with thick, black surfaces
Oxisols	Aquox	Haplaquox	≤50	Moteado	Weathered, frequently iron-rich soils, usually in tropics
Spodosols	Aquod	Alaquod Duraquod	≤50	Immokalee	Generally sandy soils formed in forests
Ultisols	Aquult	Kandiaquult Albaquult	≤50	Rains	Soils with accumulation of clay in subsurface, more acidic than Alfisols
Vertisols	Aquert	Sulfaquent Salaquent	≤50	Sharkey	Clayey soils that swell on wetting and shrink on drying

^aDescriptions of the soil series can be found at: <https://soilseries.sc.egov.usda.gov/osdname.aspx>^bNA is not applicable.**Table 3** Taxonomic groups from the World Reference Base soil classification system which may contain hydric soils.

<i>Reference Soil Group</i>			
<i>Name</i>	<i>Description</i>	<i>Examples of Principal Qualifiers</i>	<i>Examples of Supplemental Qualifiers</i>
Histosols	≥ 40 cm organic material with ≥ 20% organic carbon	Fibric/Hemic/Sapric—organic materials also called peat, mucky peat, and muck, respectively, which vary by percentage of visible fibers present. Only one used.	Hyperorganic—organic material ≥ 200 cm thick
Gleysols	Saturated with groundwater long enough to become reduced within 40 cm of surface	Stagnic—saturated with surface water long enough to become reduced and show redoximorphic features Reductigleyic—gley colors present but no features with oxidized iron (no redox concentrations)	Sulfidic—contains inorganic sulfides Humic—having ≥ 1% organic carbon to depth of 50 cm Limnic—contains organic or mineral material deposited by organisms such as diatoms or algae
Planosols	Abrupt textural change within 100 cm of surface capable of perching water, with redoximorphic features	Histic—organic material saturated with water ≥ 30 consecutive days most years Gleyic—saturated with groundwater long enough to get reduced, gley Munsell hues may be present	Capillaric—layer ≥ 25 cm thick that has so few macropores that water saturation of capillary pores causes reducing conditions Plinthic—a layer with ≥ 15% Fe nodules or nearly cemented Fe concentrations
Stagnosols	Within 25 cm of surface, layer(s) with redoximorphic features in 50% of volume, or reducing conditions	Thionic—extremely acid subsurface horizon (pH < 4) contain sulfuric acid produced from oxidation of sulfides Anthraquic (rice paddy) near surface with reduced matrix and oxidized channels	Ferric—has ≥ 15% redox concentrations within 100 cm of surface Nitric—subsurface horizon with ≥ 30% clay

IUSS Working Group WRB (2015) *World Reference Base for Soil Resources 2014*. Update 2015 International Soil Classification System for Naming Soils and Creating Legends for Soil Maps. World Soil Resources Reports No. 106. FAO: Rome.

Table 4 Summary of the classification systems used in selected countries which may contain hydric soils similar to those defined in the U.S.

Country	Soil Type	Soil Order or Equivalent	Description	Hydric Soil Occurrence
Russia	Mineral	Gley soils	Gley horizon with low chroma colors and iron mottles	When horizon is within 25 cm of surface and is at least 15 cm thick
		Hydrometamorphic soils	Hydrometamorphic horizon with olive hues without iron mottles	When horizon is within 30 cm of surface
	Organic	Peat soils	Oligotrophic, eutrophic, and dry peat soils	Most organic horizons ≥ 50 cm will be hydric
China	Mineral	Reclaimed peat soils	Drained peat soils with some alteration	Most organic horizons ≥ 50 cm will be hydric
		Gleysols	Soils with gleyic features within 50 cm of surface	Will be hydric if low chroma matrix colors occur within 25 cm of surface in horizon at least 15 cm thick in most cases
	Organic	Histosols	Organic soils similar to Histosols in <i>Soil Taxonomy</i>	Will be hydric in most cases
Australia	Mineral	Hydrosols	Most of the soil profile saturated for 2–3 months in most years	Will be hydric if low chroma matrix colors occur within 25 cm of surface in a layer at least 15 cm thick
	Organic	Organosols	Have more than 40 cm of organic materials in upper 80 cm	Most will be hydric soils
	Brazil	Gleissolos	Includes most soils with aquic suborders as defined in <i>Soil Taxonomy</i>	Will be hydric if low chroma matrix colors occur within 25 cm of surface in a layer at least 15 cm thick
		Planossolos	Similar to the Alfisols and Ultisols in <i>Soil Taxonomy</i> with aquic conditions but probably saturated for shorter periods than Gleissolos	Will be hydric if low chroma matrix colors occur within 25 cm of surface in a layer at least 15 cm thick
		Organossolos	Includes the Histosols as defined in <i>Soil Taxonomy</i>	Will be hydric in most cases

Data from McBride MB (1994) *Environmental Chemistry of Soils*. Oxford University Press: New York. Fig. 7.5, maximum Eh at which the given elements are reduced based on laboratory experiments.

In the Russian soil classification system, the saturated mineral soils are included in two categories—Gley soils and Hydro-metamorphic soils (Table 4) (Shishov et al., 2005). These orders probably differ in the durations of their saturation periods. Hydric soils as defined earlier can occur in both categories if the color patterns diagnostic of hydric soils occur within the depths shown in Table 4.

The Russian system is unique in that it identifies two categories of organic soils, essentially drained and undrained, where hydric soils can be found. A soil that has been drained is still considered a hydric soil, under the criteria used in the United States, if it retains the soil characteristics that developed when it was saturated and anaerobic. Hydric soil features associated with mineral soils such as the gray matrix colors and redoximorphic features can persist after drainage for several years because the features remain intact under aerobic soils unless physically disturbed (Hayes Jr. and Vepraskas, 2000). Conversely, organic surface layers can oxidize overtime, and if they were the features used to designate the soil as hydric, then the soil may no longer be considered hydric following organic matter oxidation (Ewing and Vepraskas, 2006). However, it is likely in such cases that the deeper mineral layers in the soils would have also developed the characteristics diagnostic of hydric soils and could be used to support a hydric designation for the soil if they occur ≤ 25 cm from the surface after the original organic layers have disappeared.

The soil classification systems used in China and Australia are similar in that hydric soils can be found in a single category in both the mineral and organic soil groups (Gerasimova, 2010; Isbell, 2002). Most of the organic soils will be hydric under these classification schemes. The mineral soils will be hydric as long as low chroma colors are found within 25 cm of the surface in layers that are at least 15-cm thick. The Brazilian soil classification system also has two categories of mineral soils, Gleissolos and Planossolos. These are similar to those described for Gleysols and Planosols in the World Reference Base system (Table 3). The Organossolos are similar to the Histosols defined in *Soil Taxonomy* and the World Reference Base systems. However, the amount of organic C required for organic soil materials in the Brazilian system is about one-half that required for hydric soils, so not all Organossolos will be hydric soils (AcervoLima, 2022).

Despite the differences that occur across these classification systems, several themes are found in all in that hydric soils are associated with: (1) the persistence of water tables near the soil surface, (2) the accumulation of organic materials, and (3) the presence of low chroma colors and/or redoximorphic features that can be used to readily identify soils formed in wetlands.

Formation of hydric soil features

Oxidation-reduction reactions govern many of the chemical processes occurring in saturated soils and sediments (McBride, 1994). Four conditions are needed for a soil to become anaerobic through reducing chemical reactions: (1) the soil must be saturated or

inundated to exclude atmospheric O₂ (oxygen); (2) the soil must contain accessible organic tissues (organic matter) that can be oxidized or decomposed; (3) a microbial population must be respiring and oxidizing the organic tissues; and (4) the water should be stagnant or moving very slowly. Saturation or inundation is needed to keep the atmospheric O₂ out of the soil. Exclusion of atmospheric O₂ is the major factor that determines when reduction can occur in the soil. Presence of oxidizable organic tissues is probably the most important factor determining whether or not reduction occurs in a saturated soil (Beauchamp et al., 1989). Some soils are known to be saturated yet do not display any signs that reducing reactions such as Fe³⁺ reduction to Fe²⁺ have occurred. In most instances, such soils simply lack the oxidizable organic tissues needed to supply the electrons used in reducing reactions (Couto et al., 1985).

A respiring microbial population is essential to the formation of reduced soils. Bacteria are widespread, abundant, varied, and adapted to function in the climates in which they occur. As reducing chemical reactions have been studied more extensively in the field, it has become clear that they occur more frequently than originally thought (Megonigal et al., 1996). Lastly, stagnant or nearly-stagnant water is needed for reducing reactions to occur (Gilman, 1994). Fast-moving water, particularly at the surface, retards the onset of reduction by supplying oxygen to the soil. While the water is in motion, its O₂ content is difficult to deplete.

Types of morphological features of hydric soils

The redox reactions that create hydric soils produce indicators, signs that are easily seen or smelled, showing that they have occurred in the soil. A 'reduced' soil is one in which redox reactions have caused reduced forms of O, N, Mn, Fe, or S (sulfur) to be present in the soil solution. 'Reduced' is a general term that implies that some elements in addition to O₂ are present in their reduced electron valence states. Common reduced forms of elements or compounds that are found in hydric soils include: H₂O (water), N₂ (nitrogen), Mn²⁺ (manganese), Fe²⁺ (iron), and H₂S (hydrogen sulfide), while their oxidized counterparts are O₂, NO₃⁻ (nitrate), MnO₄⁻ (permanganate), Fe(OH)₃ (ferric hydroxide), and SO₄²⁻ (sulfate), respectively.

Morphological features of hydric soils include specific color patterns, odors, color changes that occur on exposure to air, or a specific kind of organic material. These features can occur at any depth in the soil, and the abundance of a given feature is variable. The principal reducing reactions that form hydric soils involve four elements (O, Mn, Fe, and S), which are used as electron acceptors in anaerobic microbial respiration. Table 5 shows that there are also four basic groups of features that are associated with the principal reducing chemical reactions. These feature groups will be identified by the major element related to their formation: (a) organic-C based features, (b) Mn-based features, (c) Fe-based features, and (d) S-based features. Selected examples of morphological features of reduction are listed in Table 5 and are described below.

Organic-carbon based morphological features

Organic-carbon based features consist of one of three kinds of materials: organic, mucky mineral, or mineral soil materials with a black color. These materials form either distinct horizons (O or A horizons) or occur as aggregates of organic-rich material. The O horizon thickness and state of decomposition must be considered when identifying hydric soils. The O horizons with a thickness ≥ 20 cm and a black or very dark gray color, regardless of the state of decomposition, are in most cases found only in soils that were periodically anaerobic and reduced (United States Department of Agriculture—Natural Resources Conservation Service (USDA-NRCS), 2018). Thinner layers can also be found in seasonally reduced soils, but their thickness and state of decomposition requirements vary for different textural groups and geographic areas. The A horizons consist of mineral (occasionally mucky mineral) soil material, and those that formed in reduced soils have moist Munsell colors with a value of 3 or less and a Chroma of 2 or less (Fig. 1A). The dark color is a direct result of relatively large amounts of organic matter that accumulated under reduced conditions. However, not all soils having dark colors necessarily experience periods of saturation and reduction. This is particularly

Table 5 Reducing reactions associated with the creation of morphological features found in hydric soils.

Reducing Reaction	Approximate Eh (pH 7) ^a	Morphological Feature Formed	
	mV	Group Name	Examples
O ₂ + 4e + 4H ⁺ → 2H ₂ O ^b	600	Organic C-based features	Oa and some black A horizons
MnO ₂ + 2e + 4H ⁺ → Mn ²⁺ + 2H ₂ O	300	Mn-based features	Mn concentrations, some depletions
Fe(OH) ₃ + e + 3H ⁺ → Fe ²⁺ + 3H ₂ O	175	Fe-based features	Fe concentrations and Fe depletions
SO ₄ ²⁻ + 8e + 10H ⁺ → H ₂ S + 4H ₂ O	-200	S-based features	Odor of rotten eggs

^bReaction develops anaerobic conditions, and features form after O₂ depleted.

Modified from: United States Department of Agriculture – Natural Resources Conservation Service (USDA-NRCS). (2018) *Field Indicators of Hydric Soils in the United States (Version 8.2)*. Vasilas LM, Hurt GW and Berkowitz JF (eds.) Washington, DC: USDA-NRCS, in cooperation with the National Technical Committee for Hydric Soils.

Fig. 1 Example of the morphological features that form hydric soil field indicators. (A) Black mineral horizon formed by C accumulation creating a C-based feature. (B) Fe-based features, or redoximorphic features in the form of an Fe pore lining (redox concentration, arrow) with a gray Fe depletion in the matrix. Scale bar is 1 cm long. (C) Fe depletions along root channels (arrow) with redox concentrations (Fe masses) in the matrix. Formation of these Fe-based features is illustrated in Fig. 2. Scale bar is 1 cm long. (D) A gley-colored soil material (bluish gray color) on left as found in the soil representing a reduced matrix, Fe-based indicator. Sample on right turned red when dipyrindyl dye was applied indicating that reduced Fe was present. Scale bar is 1 cm long. Photos courtesy of John Kelley, used with permission.

true of the Mollisols found in the Midwestern United States, Ukraine, and Northeastern China, and other ecosystems characterized by grassland prairies (Bell and Richardson, 1997).

Iron and manganese-based morphological features

Redoximorphic features are formed by the reduction, movement, and oxidation of iron (Fe) and manganese (Mn) compounds (Vepraskas, 2015; Vepraskas and Vaughan, 2016). These features form the gray, red, yellow, brown, or black mottled color patterns that are normally associated with saturated and reduced soils. Redoximorphic features are the most widely observable morphological features formed by reduction, and are most commonly used to identify the spatial extent of hydric soils in the landscape. There are three basic kinds of redoximorphic features: redox concentrations, redox depletions, and the reduced matrix.

Redox reactions affect Fe and Mn similarly, and the two elements frequently occur together. Manganese minerals are black in their oxidized form, whereas oxidized Fe minerals are generally yellow, brownish red, or red. Iron is usually in greater abundance than Mn, but small quantities of Mn can cause some redox concentrations to appear black (Gallaher et al., 1974). Manganese can be abundant in certain soils, such as those with a pH >7, or in some clay soils having Munsell hues of 5YR or redder (e.g., Moreland series reported in Hudnall et al., 1990). When Mn is abundant, it can prevent the reduction of Fe and the formation of gray soil

colors because it is reduced before Fe (McBride, 1994). The remainder of this discussion will focus on Fe, but Mn should also be assumed to be included because it is subject to the same processes.

Redox concentrations

Redox concentrations are features formed when Fe oxides or hydroxides have accumulated at a point or around a large pore such as a root channel (Fig. 1B). They have been defined as “bodies of apparent accumulation of Fe-Mn oxides and hydroxides” (Vepraskas, 2015). This means that they appear to have formed by Fe or Mn moving into an area, oxidizing, and precipitating. Redox concentrations contain more Fe³⁺ oxides and hydroxides than were found in the soil matrix originally. Three kinds of redox concentrations have been defined: Fe pore linings, Fe masses, and Fe nodules and concretions. These differ in their hardness and also in where they occur in the soil.

Pore linings are accumulations of Fe oxides and hydroxides that lie along ped surfaces or root channels (Fig. 1B). These features occur in the soil and not directly on the root. They are similar to oxidized rhizospheres, but these are thought to form on root tissue while the root is alive (Mendelsohn et al., 1995), whereas pore linings do not need a live root in order to form.

Iron masses are simply soft accumulations of Fe³⁺ oxides and hydroxides that occur in the soil matrix, away from cracks or root channels (Fig. 1C). They can be of any shape. The masses are easily crushed with the fingers because the concentration of Fe is not great enough to cement the soil particles into a solid mass. Pore linings differ from iron masses only in where they occur in the soil: masses occur in the matrix, while the pore linings must be along root channels or cracks. The colors of the two features are similar.

Nodules and concretions are hard, generally spherical-shaped bodies made of soil particles cemented by Fe oxides or hydroxides. They range in size from less than 1 mm to over 5 cm in diameter. When broken in half and examined, the concretions are seen to consist of concentric layers like an onion, while no layers are seen in nodules. Most people seem to use the two terms interchangeably, and there is no special significance attached to the layered structure other than it shows that the concretion formed in episodes over time.

Redox depletions

Redox depletions are zones formed by the loss of Fe and other components (Fig. 1C). They have been defined as “bodies of low Chroma (<2), having values of 4 or more where Fe-Mn oxides alone have been stripped out or where both Fe-Mn oxides and clay have been stripped out” (Vepraskas, 2015). This definition is used to meet the soil classification requirements for aquic conditions as set out in *Soil Taxonomy* (Soil Survey Staff, 2014). Redox depletions in principle could form with Chromas >2 as long as they developed in a soil horizon whose matrix lost Fe by chemical reduction processes.

Reduced matrix

The reduced matrix has been defined as a soil matrix that has a “low chroma color *in situ* because of the presence of Fe²⁺, but whose color changes in hue or chroma when exposed to air as the Fe²⁺ is oxidized to Fe³⁺” (Vepraskas, 2015). The time needed for the color change to occur was set for practical reasons at 30 min, because waiting longer would interfere with the completion of field work. However, there are few data on how long such color changes require and changes often occur following only a few minutes of exposure to oxygen. The *United States Army Corps of Engineers* (U.S. Army Corps of Engineers (USACE), 2012) provides guidance for identifying a reduced matrix in the field. It can also be detected by spraying a field moist sample of soil with a dye such as α , α' -dipyridyl that reacts with Fe²⁺ (Fig. 1D). If a positive reaction with the dye occurs, then it should be assumed that a reduced matrix is present.

Gley soil colors

Gley colors consist of Munsell hues found on the “Gley Pages” of a Munsell Color Chart that display a value of 4 or more. If the color of the soil does not change on air drying, the material with the gley hue is probably a redox depletion (e.g., Fe depletion). This occurs when the Fe is reduced, translocated and therefore removed so that it is no longer present in the soil matrix. If a color change (e.g., reddening of the matrix) occurs on drying, the material is probably a reduced matrix. A reduced matrix indicates the Fe is reduced but not translocated from the soil matrix so that with exposure to oxygen, the iron is oxidized to a colored form.

The gley hues can, in some cases, be unique minerals that contain a reduced form of Fe that is combined with an anion of phosphate, sulfate, carbonate, or other compound (Schwertmann and Taylor, 1989). These hues are a morphological indicator of reduction when their values are 4 or more. When values are less than 4, the colors are probably too dark to separate gley hues accurately from other kinds of soil features.

Formation of redoximorphic features

Redoximorphic features are found in most mineral hydric soils. They form after one or more of the following three processes have occurred: (1) Fe³⁺ cations in oxides or hydroxides have been reduced, (2) the solubilized Fe²⁺ has moved to another portion of the soil, and (3) the Fe²⁺ has been oxidized to form an Fe mass, pore lining, or nodule. A reduced matrix requires that only the first step occurs. Iron depletions require that the first two steps occur, while formation of redox concentrations requires that all three steps occur.

Redox depletions: The process of redox depletion formation is shown in Fig. 2. Prior to forming depletions the soil matrix had a uniform brown color throughout. The color came from Fe³⁺ oxide or hydroxide minerals that coated soil particles, such as

Fig. 2 Formation of redox depletions (Fe depletions) around a root channel. Initially (A) the soil is uniformly brown throughout its matrix. The channel contains a dead root, which is being decomposed by bacteria. Upon flooding (B), the channel is filled with water, and all O₂ dissolved in the water is reduced. When the water is anaerobic, the bacteria reduce Fe oxides and hydroxides in the soil surrounding the channel. The Fe²⁺ dissolves and moves away from the channel (C) leaving the soil particles around the channel stripped of the Fe coatings. If the stripped grains are largely composed of quartz and/or uncoated clay minerals, they will be gray in color (D). The Fe²⁺ may subsequently oxidize to form a reddish brown Fe mass. Adapted from Vepraskas MJ (2015) *Redoximorphic Features for Identifying Aquic Conditions*. Technical Bulletin 301, North Carolina Agricultural Research Station: Raleigh, NC.

sand, silt, and clay grains. Each of these grains had a coating of an Fe³⁺ compound that effectively painted the particle surface brown.

The soil shown in Fig. 2A has a channel containing a dead root that is being decomposed by bacteria. If the channel is filled with air, oxidation of the organic matter releases electrons which are used to reduce O₂ to water. Provided that the channel contains air, the only reduction that takes place is that of O₂ to water, and there is no change in the color of the soil around the root.

If the channel fills with water, however, the supply of O₂ from the atmosphere is cut off (Fig. 2B). Microbial respiration still occurs, and the organic tissue continues to be oxidized. The O₂ dissolved in the soil water is quickly depleted because it is the primary electron acceptor used in the respiration process. After O₂ is depleted, the water becomes anaerobic, and electrons generated during microbial respiration begin to interact with alternative electron acceptors (e.g., Fe³⁺), which induces a change in soil color.

When the electrons are transferred to Fe³⁺ atoms in oxides or hydroxides, the reduction of the Fe causes two changes in the minerals: they lose their color and the Fe²⁺ dissolves. The dissolved Fe²⁺ moves off the particle surfaces and may diffuse through the soil matrix, or it may be carried to other parts of the soil in moving water (Fig. 2C). As Fe²⁺ leaves the particle surfaces, the color of the soil around the channel changes and the soil gradually becomes gray in color. In Munsell terminology the soil Chroma decreases and Value increases until all Fe has been removed from the surfaces of particles lying near the channel. When the soil drains and O₂ enters the soil, the newly formed Fe depletion feature will retain its gray color because it is the color of the uncoated mineral soil grains. Oxygen penetrating into the matrix may oxidize the Fe²⁺ and cause the formation of pore linings or Fe masses elsewhere in the soil profile (Fig. 2D).

Stripping the soil particles of Fe³⁺ mineral coatings changes the soil's color to the natural color of the soil minerals (i.e., the 'naked grain'). Normally this is a gray color when the particles consist of quartz or a clay mineral such as kaolinite. This gray color is relatively permanent and is not affected appreciably by additional periods of saturation and reduction. The only way the color of the gray soil particles could become brown again is if Fe²⁺ were moved onto the particle surfaces and reoxidized to recoat the particle surfaces with more of the 'paint' composed of Fe³⁺ minerals.

This is the basic process that forms redox depletions. It is easiest to see in the field when the organic matter occurs as a root (Fig. 1C). In such cases the gray depletions form cylindrical features around root channels. However, if roots are closely spaced along a crack or ped surface, then the depletions will have a planar shape as they coat the surface of the crack, or they may occupy entire layers.

In A horizons the organic matter that starts the depletion formation can be a piece of leaf tissue or a fragment of some other part of the plant. This is an isolated source of organic tissue. The depletions that form around this tissue tend to be spherical. The processes that form the depletion are the same as those shown in Fig. 2.

Field indicators of hydric soils

The chemical reactions that create anaerobic conditions as well as Fe reduction in near surface layers, create unique hydric soil characteristics that can be seen, felt, or smelled as listed in Table 6. These characteristic features are used to identify hydric soils at wetland sites by using *Hydric Soil Field Indicators* (United States Department of Agriculture—Natural Resources Conservation Service (USDA-NRCS), 2018). They are applied in conjunction with indicators of hydrophytic vegetation and wetland hydrology to identify wetlands for a variety of natural resource management applications (U.S. Army Corps of Engineers (USACE), 2012; Tiner, 2016).

The field indicators of hydric soils specify combinations of soil horizon thickness, color, and redoximorphic feature characteristics, known to develop when soils form in areas subject to prolonged saturation and anaerobic conditions, therefore linking soil morphology with the definition of hydric soils. The field indicators also include information about the soil texture and the region of the United States where the field indicator can be applied. For example, the field indicator S5—Sandy Redox states the following:

“S5—Sandy Redox. For use in all LRRs [Land Resource Regions], except for W, X, and Y. A layer starting at a depth ≤ 15 cm (6 inches) from the soil surface that is at least 10 cm [4 inches] thick and has a matrix with 60% or more chroma of 2 or less and 2% or more distinct or prominent redox concentrations occurring as soft masses and/or pore linings.”

The field indicators of hydric soils were developed for three different textural groups indicated by the alphanumeric designation (e.g., S5) associated with each indicator. Field indicators designated with an ‘A’ (i.e., all soil types) can be applied to soil layers (or a combination of layers) composed of organic materials or any mineral soil textures; indicators designated with an ‘S’ (i.e., sandy soil) are only applicable in mineral soil layers composed of USDA soil texture classes sand, fine sand, very fine sand, loamy coarse sand, loamy sand, and loamy fine sand; and indicators designated with an ‘F’ (i.e., fine soil) are applicable to all mineral soil textures not addressed by the ‘S’ indicators.

This system reflects soil texture and organic matter contents, and is not directly related to any soil classification system. It accounts for the different water holding capacities and capillary fringe potentials that vary with soil texture, and allows for the application and use of multiple field indicators of hydric soils within soil profiles composed of varying soil textures. The field indicator names provide insight into the general characteristic(s) of the indicator. For example, S5—Sandy Redox requires a sandy soil texture and the presence of redoximorphic features.

The geographic area where a given field indicator of hydric soils can be applied in the United States is defined using Land Resource Regions (LRRs) and Major Land Resource Areas (MLRAs) (United States Department of Agriculture, Natural Resources Conservation Service, 2006). For example, the field indicator S5—Sandy Redox can be applied in all areas of the United States except in Alaska (LRRs W, X, Y). This approach recognizes the differences in pedogenic processes and morphology related to varying climate, parent materials and other factors that occur across the United States. Field indicators approved for cold regions with short growing seasons where microbial activity is depressed require thicker organic matter layers compared with field indicators applied in hot, tropical climates where the year-round growing season and increased microbial respiration limit the accumulation of carbon in most soils. The LRRs are based largely on soil temperature regimes, soil moisture regimes, and physiography, and can be extrapolated to other parts of the world using the definitions of the regions given in United States Department of Agriculture, Natural Resources Conservation Service (2006).

The guidance document “Field Indicators of Hydric Soils in the United States” currently identifies 45 field indicators of hydric soil approved for use, as well as several field indicators approved for testing. Indicator “F3—Depleted matrix” is the field indicator

Table 6 Common field indicators of hydric soils in the United States.

Indicator	General diagnostic characteristics
A1—Histosol	Soil layers composed of organic material ≥ 40 cm thick occurring within the upper 80 cm of the soil surface
A11—Depleted Below Dark Surface ^a	A gray or gley soil layer with a depleted matrix ≥ 15 cm thick beginning within ≤ 30 cm of the soil surface. Soil layers above the depleted matrix must be dark (i.e., Munsell value ≤ 3 , Chroma ≤ 1 for sands; Value ≤ 3 , Chroma ≤ 2 for all other textures)
A4—Hydrogen Sulfide Odor	A hydrogen sulfide odor encountered within ≤ 30 cm of the soil surface
F3—Depleted Matrix ^a	A gray or gley loamy/clayey soil layer with a depleted matrix either ≥ 5 cm thick beginning within ≤ 10 cm of the soil surface, or ≥ 15 cm thick beginning within ≤ 25 cm of the soil surface
F13—Umbric Surface ^a	A dark loamy/clayey soil layer ≥ 15 cm thick beginning within ≤ 15 cm of the soil surface with Munsell value 3 or less and Chroma 1 or less, and immediately underlain by a layer ≥ 10 cm thick with Chroma of ≤ 2
S5—Sandy Redox ^a	A sandy soil layer ≥ 10 cm thick beginning within ≤ 15 cm of the soil surface with Chroma ≤ 2 and $\geq 2\%$ redoximorphic concentrations

^aField indicators commonly observed at the hydric soil boundary (i.e., often used for hydric soil delineation)

Modified from Berkowitz JF, Vepraskas MJ, Vaughan KL and Vasilas LM (2021) Development and application of the Hydric Soil Technical Standard. *Soil Science Society of America Journal* 85: 469–487.

Fig. 3 Example of how hydric soil field indicators are used to identify hydric soil boundaries. The Coastal Plain landscape is nearly level with an elevation change of approximately 30 cm. The soil scientist begins by examining soil near the center of the wetland, which in this example is shown in (A). This soil meets the hydric soil field indicator Umbric Surface. Having confirmed the site had a hydric soil, the soil scientist moves toward the edge near the upland. Near the edge, the soil described is shown at (B), and this met the hydric soil field indicator Depleted Matrix. From this point the soil scientist walks up the slope into the upland and examines the soils. In this landscape, the soil at (C) occurred, and this did not meet a hydric soil field indicator. The hydric soil boundary occurred between soils (B) and (C). The boundary was placed at the base of the slope, because soil borings showed that field indicators were not met on the slope.

most frequently used to identify hydric soils and delineate their boundaries (Berkowitz, 2011). As its name implies, the depleted matrix has a matrix formed by redox depletion with a high Munsell Value (≥ 4) and low Chroma (≤ 2), causing the soil to appear gray. Redox concentrations are also required in A and E horizons.

To delineate the hydric soil boundary using the field indicators of hydric soils, practitioners typically begin in wetter areas, identify the diagnostic characteristics associated with one or more of the field indicators, then move upslope in the landscape along a line toward drier areas, examining the soil periodically until the diagnostic criteria are no longer met. For example, when applying a field indicator that requires a Munsell Chroma ≤ 2 and $\geq 2\%$ redoximorphic features, the hydric soil boundary occurs at the location where either the chroma exceeds 2.0 or the soil first exhibits $<2\%$ redoximorphic features.

This approach is illustrated in Fig. 3 which shows a landscape described by Hayes Jr. and Vepraskas (2000). The Coastal Plain landscape is almost level with small changes in elevation that separate wetland areas from uplands as shown. Soil A in Fig. 3 occurs in the wetland center and meets the hydric soil field indicator called “Umbric Surface” which is characterized by a black A horizon (10YR 3/1) beginning at the mineral surface. It is underlain by material with a Chroma of 2 or less. At the edge or hydric soil boundary, soil B meets the hydric soil field indicator termed the ‘Depleted Matrix’ characterized by a layer at a depth of 20–35 cm with a color of 10YR 4/2 and approximately 2% redox concentrations seen as orange mottles. Between soils B and C in Fig. 3, no soil meets a hydric soil field indicator because the subsoils lose their low (≤ 2) chroma color. The boundary of the hydric soils in this landscape would be placed where the elevation starts to rise to approximately 30 cm (i.e., base of slope) and the soil color changes occur.

The hydric soil technical standard

Over the past several decades, research in soil science has linked the unique biogeochemical processes occurring in wetlands with the distinct morphological patterns occurring in hydric soils (Vepraskas and Vaughan, 2016). This research facilitated development of the field indicators of hydric soils described above, which are approved by the National Technical Committee for Hydric Soils

Table 7 Summary of the sampling techniques and minimum technical requirements of the Hydric Soil Technical Standard.

Measurement Technique	Property Criteria
Anaerobic conditions criteria	
Alpha-alpha dipyridyl dye	A positive dye reaction during two applications that occur 2 weeks apart. The reaction occurs within a 10 cm thick layer in the upper 30 cm for most soils, a 6.25 cm thick layer within the upper 12.5 cm in sandy soils, or a 5 cm layer within the upper 10 cm in soils that flood or pond.
IRIS devices	At least three of IRIS tubes must show a minimum of 30% iron removal within a zone 15 cm or more thick. The zone of removal must begin within 15 cm of the soil surface. Tubes should be deployed for a minimum of one wet-dry cycle not to exceed one growing season.
Pt electrodes	A minimum of 3 of 5 Pt electrodes display Eh values below the threshold defined by $Eh < 595 - 60(\text{pH})$. Pt electrodes are installed 25 cm for most soils, 12.5 cm in sandy textured soils, and 10 cm in soils that inundate by flooding or ponding.
Soil saturation, flooding, or ponding criteria	
Shallow groundwater monitoring wells	Soil saturation occurs within 25 cm of the soil surface for ≥ 14 consecutive days in most soils. Vertisols in Louisiana and Texas require soil saturation for ≥ 7 consecutive days with saturation occurring $\geq$ days annually.
Precipitation normality criteria	
Analysis of precipitation normality	Analysis using the Direct Antecedent Rainfall Evaluation Method, Moving Total Antecedent Rainfall Method, or Adjusted Moving Total Antecedent Rainfall Method to determine whether the study occurred during a period of normal, above-normal, or below-normal precipitation based on the 30th and 70th percentile averages from 30-year precipitation records (Sumner et al., 2009).

(NTCHS) for application in the United States. To ensure that field indicators of hydric soils are defensible, the NTCHS developed a scientifically based and repeatable approach to evaluate the hydric status if a soil known as the Hydric Soil Technical Standard (HSTS). The HSTS provides a mechanism to: (1) initiate new field indicators of hydric soils, (2) alter existing field indicators, (3) identify hydric soils in areas lacking an approved field indicator, and (4) evaluate the current functional status of a hydric soil. For example, Berkowitz and Sallee (2011) utilized the HSTS to propose a new field indicator for an area that contained hydric soils but that did not meet a currently approved field indicator, and also expanded the applicable region of several other field indicators with HSTS data. The HSTS documents that a soil is saturated and anaerobic, thus demonstrating that the soil meets the definition of a hydric soil noted earlier (Berkowitz et al., 2021). As a result, the HSTS requires that three technical criteria be met: (1) anaerobic conditions; (2) soil saturation in the upper 25 cm of the soil profile for at least 14 consecutive days for most soils, or for 7 consecutive days occurring for a minimum of 28 days annually for Vertisols in Louisiana and Texas; and (3) the saturation and anaerobic conditions criteria must be met following a period of normal or drier than normal precipitation when soil microbes are active.

Under the HSTS framework, practitioners document the durations of anaerobic conditions and saturation. Precipitation must also be recorded to determine if the anaerobic and saturated conditions occur during wet, normal, or dry years using a variety of techniques (Sumner et al., 2009). The HSTS documents whether or not a soil currently functions as a hydric soil and does not address the conditions under which the soil formed. As a result, the HSTS is not designed or intended to be used to overrule or invalidate a hydric soil determination based on the presence of one or more field indicators of hydric soils. The field indicators reflect natural processes that develop over time during soil formation and generally provide the best evidence that hydric soils are present on a site. However, the NTCHS acknowledges that some hydric soils do not display approved field indicators of hydric soils for a variety of reasons (e.g., problematic parent materials, recently deposited or disturbed soils). In such cases, the HSTS is a valuable tool to evaluate the current hydric status of those soils. In addition, application of the HSTS improves our understanding of hydric soil function and morphology across a variety of environmental gradients, management scenarios, and disturbance regimes (Table 7).

Summary

Hydric soils form in wetlands where saturation persists long enough to create anaerobic conditions. The presence of anaerobic conditions induces changes in soil morphology that have been used to develop diagnostic criteria in support of wetland protection laws in the United States and elsewhere. Soil classification systems provide useful corollaries to identify areas where hydric soils are likely occur, based on the presence of aquic conditions, carbon accumulation, or the transformation and translocation of redox active elements such as Fe and Mn. The hydric soil field indicators incorporate a variety of characteristics such as redoximorphic features to help locate wetland boundaries in support of natural resource management. In cases where field indicators of hydric soils are absent, the Hydric Soil Technical Standard provides a mechanism to link observed hydric soil morphologies with biogeochemical processes and ecological functions.

Abstract

Wetland ecosystems occur at the interface between aquatic and terrestrial ecosystems. The soils in wetlands are periodically or permanently saturated with water that excludes oxygen from the soil environment. Therefore, only vegetation adapted to growth in these saturated conditions are able to survive in wetland ecosystems. Wetland soils have unique chemistry due to the deficiency of oxygen, where microorganisms utilize electron acceptors other than oxygen in respiration. The reduced elements thus produced, specifically Mn^{2+} (manganese) and Fe^{2+} (iron) become mobile and are redistributed, resulting in unique redox morphology. It is this morphology that is used to characterize wetland soils.

Glossary

Aerobic An environment in which molecular oxygen is present (rH greater than 20).

Anaerobic An environment in which molecular oxygen is essentially absent (rH less than 20).

Drained wetland A wetland where ground or surface water was artificially removed.

Flooded soil Where the soil surface is temporarily covered with water from any source, e.g., from streams, upslope, tides, or a combination thereof.

Frequently flooded, ponded or saturated soil Flooding, ponding, or saturation is likely to occur often under the normal weather conditions (i.e., >50% probability in any year, or >50 times in 100 years).

Gleyic color pattern Bright (Munsell color chroma >2) macro pores that form due to oxidation, with grey (Munsell color chroma ≤2) matrices that form due to reduction, indicative of longer periods of ground water saturation.

Hydric soil A soil that formed under conditions of water saturation, flooding, or ponding long enough during the growing season to develop anaerobic conditions.

Long duration A single event that lasts from 7 days to 1 month.

Stagnic color pattern Grey (Munsell color chroma ≤2) macro pores that form due to reduction, with bright matrices (Munsell color chroma >2) that form due to oxidation, indicative of shorter periods of surface water saturation.

Very long duration A single event that lasts longer than 1 month.

Key points

- Wetlands form at the interface between aquatic and terrestrial ecosystems.
- Water saturation in wetland soils excludes oxygen from these environments.
- Only vegetation adapted to these water saturated conditions can therefore survive.
- Anaerobic microorganisms additionally reduce elements such as Mn^{2+} (manganese) and Fe^{2+} (iron).
- These processes can lead to unique soil chemistry and morphology, known as redox morphology.

Introduction

Wetlands are defined as ecosystems that occur at the interface between the terrestrial (upland) and the aquatic (water) ecosystems. Therefore, they occur where land and water meet, and thus have alternating aerated and water saturated conditions in their soils. The habitat in wetlands is therefore neither fully aquatic nor fully terrestrial. The soils in wetlands thus have too much water, resulting in the exclusion of air that causes a deficiency in oxygen. The net effect is that only plants that have adapted physiologically and morphologically to growth in water saturated soil environments can survive. Because wetlands occur at the interface between terrestrial and aquatic ecosystems they are typically found lower in the landscape along rivers, lakes, bays, and deltas. They can, however, also occur higher up in the landscape in depressions where artesian water typically accumulates.

Globally, inland and coastal wetlands comprise more than $12.1 \times 10^6 \text{ km}^2$ of the land surface, of which 54% is permanently inundated while 46% is seasonally inundated. The areal extent of natural wetlands has declined by about 35% since 1970, whereas the areal extent of human-made wetlands (mainly for paddy field rice production and water reservoirs) have almost doubled now to comprise 12% of all wetlands.

Traditional attitudes to wetlands are quite negative, as reflected in words such as 'bogged down,' 'swamped,' 'muddied,' 'mired,' 'murky,' 'morass,' 'malarial,' and 'quagmire.' Wetlands have thus historically been treated as wastelands that need to be drained or filled in order to be farmed or to be built upon (the latter is a probable source of the word 'landfill' constructed on a 'wasteland'). Drainage schemes, from large government initiatives to small local endeavors, to rid wetlands of 'excess' water have therefore dominated the historic approach of humans to wetlands. Recently however, human perception of wetlands has changed to recognize the many vital functions and ecosystem services that they provide within the broader environment. These wetland ecosystem services include providing a wildlife habitat, flood water and erosion control, aesthetics and recreation facilities, areas for carbon sequestration, and high biological productivity.

It is estimated that 50% of all the wetlands in the United States have been drained since colonial times and that 90% of all present-day agricultural lands in the United Kingdom were former wetlands. Wetlands therefore remain under threat either from direct or indirect causes. Indirect causes such as sea-level rise can inundate coastal wetlands, while direct causes include changes in wetlands' hydrological regimes due to upstream water extraction, construction of dams, dikes, or levees, which all reduce the water supply to downstream wetlands.

Wetlands are typically defined by the presence of wetland vegetation, wetland soils, and or topographical position. It is, however, in the soil where water saturation occurs and controls the alternating oxidizing and reducing environments. It is further possible that the wetland vegetation can be destroyed, leaving soil and topography as the only two permanent wetland indicators. The excessive water in wetland soils causes anaerobic conditions that lead to a decrease of the redox potential. It is the latter that results in differential reduction of certain soil constituents, leading to unique soil morphology that can be utilized in the identification of wetlands. These morphological features can persist for centuries in the soil, even after a wetland has been drained.

The Ramsar Convention (Ramsar, 1971) defines wetlands as "areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water the depth of which at low tide does not exceed six meters". It is, however, also important to note that the definition of wetland differs between, and often within, countries. These definitions may further vary in complexity from legislative ones to loose anecdotal concepts.

Ramsar convention

The Ramsar Convention on Wetlands (since it was signed in 1971 in the Iranian city of Ramsar) came into force in 1975 and is the only international agreement that is focused primarily on wetlands (Ramsar, 1971). To date, 170 countries have joined the Ramsar Convention as Contracting Parties, incorporating 2300 sites that cover about $250 \times 10^6 \text{ ha}$ (Ramsar Convention on Wetlands, 2018). Obligations of the Contracting Parties include: Conservation and wise use of all wetlands (Pillar 1), Designating and conserving at least one Wetland of International Importance, known as a Ramsar Site (Pillar 2), and Cooperation across national boundaries on transboundary wetlands, shared wetland systems, and shared species (Pillar 3).

The Ramsar Convention further provides a framework for wise use to ensure that wetlands are on the global agenda, to secure the sustainable development thereof, and that support initiatives for biodiversity increase, and to ensure the mitigation of climate change, disaster risk, and land degradation. These initiatives are also in accord with the United Nations' Sustainable Development Goals, the Aichi Biodiversity Targets, the Paris Agreement on Climate Change, and other related international commitments.

The ecological character of wetlands ("the combination of the ecosystem components, processes and benefits/services that characterize a wetland at a given point in time") is a further key Ramsar concept. Ramsar Site wetlands need to be actively maintained to preserve their ecological character and therefore the participating countries have to report any negative human impacts on such sites to the Ramsar Secretariat and must further take remedial action to restore them to their former state.

Classification

Various wetland classifications exist, but most of these divide wetlands based on their relationship to water bodies. The Ramsar Convention (Ramsar Convention on Wetlands, 2018) classifies 42 wetland types into three main categories, namely marine and

Table 1 The Ramsar Convention classification of wetland categories and types.

<i>Inland wetlands</i>	<i>Coastal/marine wetlands</i>	<i>Human-made wetlands</i>
River Stream	Salt Marsh	Reservoir
Lake	Mangrove	Rice Paddy
Peatland	Seagrass	Wet Grass
Marsh Swamp	Coral Reef	Waste Ponds
Underground	Shellfish Reef	Salinas
	Lagoon	Aqua Ponds
	Kelp	

Adapted from Ramsar Convention on Wetlands, 2018.

coastal wetlands, inland wetlands, and human-made wetlands (Table 1). These wetland categories are further subdivided into wetland types. Many of the wetland types, for example, the Marine, River Stream, and Lake Wetlands are primarily aquatic and the soil is therefore permanently covered with water of up to six meters deep. These permanently inundated soils therefore do not experience the alternating cycles of oxidation and reduction, typically associated with terrestrial wetlands. The terrestrial wetlands e.g., Marsh and Peatland Wetlands contain hydric soils that form in the interface between oxidizing and reducing environments and are discussed later.

The Cowardin classification (Cowardin et al., 1979) classifies wetlands into five environments, namely Marine, Riverine (along rivers and streams), Lacustrine (along lakes), Estuarine (along tidal coasts and rivers), and Palustrine (inland freshwater forested and non-forested) wetlands. The first three (Marine, Riverine, and Lacustrine) wetlands classes are predominantly aquatic and therefore would have little or no soil development. It is thus only the Estuarine and Palustrine wetlands that would contain wetland soils.

Estuarine wetlands

Estuarine Wetlands refer to inter-tidal salt and brackish low and high marsh zones, non-vegetated tidal flats, brackish waters of coastal rivers and coastal areas, and mangrove swamps, comprising about 80 different tree species. The estuarine wetlands are subdivided into the emergent wetlands and the shrub wetlands. The estuarine emergent wetlands are dominated by herbaceous grasses and are referred to as salt marsh, low marsh (intertidal marsh), high marsh, and brackish tidal marsh, normally found in protected coastal areas or behind barriers where water movement has slowed. Many were formed due to sea level rise. There is typically a strong zonation of plant species in salt marshes, depending on the frequency and duration of inundation. The estuarine shrub wetlands have woody vegetation such as marsh elder or high tide bush, typically adapted to a saline environment. Mangrove swamps are included in this category.

Palustrine wetlands

The majority of freshwater wetlands falls under the Palustrine Wetlands and includes marshes, bogs, swamps, and ponds, with water bodies <2 m deep also included. Palustrine emergent wetlands are dominated by herbaceous vegetation with different species of grasses, rushes, and sedges. They are also known as freshwater marshes, wet meadows, and fens. The marshes may be infrequently to permanently flooded with water. Palustrine wetlands are subdivided into the emergent, shrub, and forested wetlands. The palustrine emergent wetlands have a variety of habitats, including peatlands and freshwater marshes. The palustrine shrub wetlands are characterized by woody vegetation <6 m tall, such as bog laurel (*Kalmia polifolia* Wangegh), labrador tea (*Rhododendron groenlandicum*), cranberry (*Oxycoccus palustris*), and leatherleaf (*Chamaedaphne calyculata*), and with stunted trees such as black spruce (*Picea mariana*), larch (*Larix laricina*), and balsam fir (*Abies balsamea*). Palustrine forested wetlands have trees >6 m tall, with tree species such as red maple (*Acer rubrum*), pin oak (*Quercus palustris*), sweet gum (*Liquidambar styraciflua*), black spruce (*P. mariana*), and larch (*L. laricina*).

Ecosystem services

The value of wetlands to human well-being has traditionally been ignored. It is only recently that this value has been recognized and categorized as provisioning, regulating, cultural, and supporting services (Table 2).

Wetland provisioning ecosystem services (Table 2) consist of food, fish, water, fiber, and fuel production. The regulating services determine climate and hydrological regimes, and reduce pollution, and the risk of disaster. The services of cultural importance include spiritual and inspirational services, as well as aesthetic spaces for recreation and education. Supporting services consist of biodiversity, soil formation, nutrient cycling, and pollination.

The value of wetland ecosystem services far exceeds that of terrestrial ecosystems, with the total economic value of inland wetlands being almost five times higher than that of tropical forests, the next most valuable terrestrial habitat. Estimated economic losses from 1997 to 2011 due to loss of wetland ecosystem services were US\$7.2 trillion from tidal marshes and mangroves, US\$2.7

Table 2 Summary of the wetland ecosystem services.

<i>Provisioning services</i>	<i>Regulating services</i>	<i>Cultural services</i>	<i>Supporting services</i>
Food	Climate	Spiritual and inspirational	Biodiversity
Fresh water	Hydrological	Recreational	Soil formation
Fiber and fuel	Pollution control	Aesthetic	Nutrient cycling
Biochemical products	Erosion protection	Educational	Pollination
Genetic materials	Natural hazards		

trillion from swamps and floodplains, and US\$11.9 trillion from coral reefs (Costanza et al., 2014). These estimates were made by assessing the trade-offs required to achieve a common goal in the absence of wetlands (Farber et al., 2002; Costanza et al., 2014).

Chemistry

The major difference between terrestrial and wetland soils is that wetland soils experience alternating periods of water saturation, resulting in alternating aerobic and anaerobic conditions, while terrestrial soils typically experience primarily aerobic conditions (Terrestrial soils may experience short periods of anaerobic conditions, but these are normally too short to affect the soil morphology.). Wetland soils therefore have unique chemistry because they are in environments where oxygen concentrations fluctuate between aerobic and anaerobic conditions (Mitsch and Gosselink, 2015; Ponnampereuma, 1972; Richardson and Vepraskas, 2000).

In aerobic terrestrial soils, the aerobic soil microorganisms utilize oxygen as an electron acceptor in the oxidation of organic matter to extract the latent energy from their organic matter food source. Conversely, in wetland soils that lack oxygen due to water saturation, anaerobic and facultative anaerobic microorganisms can utilize other electron acceptors in the oxidation of organic matter to extract energy. These electron acceptors are utilized in a fixed sequence that ensures maximum energy extraction (Table 3). The result is that these electron acceptors are reduced in a sequence that releases increasingly less energy, with each reduction half reaction providing increasingly less energy to the microorganisms, since the reaction has a lower redox potential. This reduction sequence is therefore determined by the redox potential of each reduction half reaction and therefore governs the possible energy released from the oxidized organic matter. The presence of large quantities of a preceding electron acceptor might therefore prevent the reduction of an electron acceptor that would release less energy, buffering or poisoning the soil system at a specific redox potential. The reduction half reactions possible in soil are similarly limited by oxygen at the higher and by hydrogen at the lower redox potential; oxygen will not be limiting in an oxidized environment, while hydrogen will not be limiting in a water-saturated environment.

In soil reduction reactions, organic matter is always the electron donor (the entity being oxidized). The organic matter being oxidized in the oxidizing half reaction originates from that produced through photosynthesis which enters the soil where it is then humified through various processes. The sources of this organic matter are variable, but can include dead plant roots, plant debris (leaves, pieces of roots), dissolved organic carbon, and/or the excreta of organisms. Oxidation of organic matter in aerobic or anaerobic respiration therefore comprises the final step in the humification process.

The simplified oxidation half reaction:

Since the reduction reactions take place in a specific sequence, it follows that oxidation of the reduced species will take place in the reverse sequence, with the last species to be reduced being the first to be oxidized. In the oxidation of the reduced elements, oxygen (O_2 , present in aerated environments) is the oxidizing agent that is in turn being reduced. The elements being reduced and the sequences of these reduction and oxidation reactions are the main causes of the unique morphology observed in wetland soils that are addressed in the next section.

Table 3 The sequence of reducing (left to right) and oxidizing (right to left) half reactions possible in wetland soils.

<i>Element</i>	<i>Half reaction</i>	<i>Expected soil redox potential (Eh, mV)</i>
Oxygen	$\text{O}_2 + 4\text{H}^+ + 4\text{e}^- \rightleftharpoons 2\text{H}_2\text{O}$	600–400
Nitrogen	$2\text{NO}_3^- + 12\text{H}^+ + 10\text{e}^- \rightleftharpoons \text{N}_2 + 6\text{H}_2\text{O}$	500–200
Manganese	$\text{MnO}_2 + 4\text{H}^+ + 2\text{e}^- \rightleftharpoons \text{Mn}^{2+} + 2\text{H}_2\text{O}$	400–200
Iron	$\text{Fe}_2\text{O}_3 + 6\text{H}^+ + 2\text{e}^- \rightleftharpoons 2\text{Fe}^{2+} + 3\text{H}_2\text{O}$	300–100
Sulfate	$\text{SO}_4^{2-} + 10\text{H}^+ + 8\text{e}^- \rightleftharpoons \text{H}_2\text{S} + 4\text{H}_2\text{O}$	0 to –150
Carbon	$\text{CO}_2 + 8\text{H}^+ + 8\text{e}^- \rightleftharpoons \text{CH}_4 + 2\text{H}_2\text{O}$	–150 to –220
Hydrogen	$2\text{H}^+ + 2\text{e}^- \rightleftharpoons \text{H}_2$	–150 to –220

Adapted from Bohn et al., 2002.

Based on the discussion above, there are four prerequisites for reduction in a wetland soil, namely: anaerobic conditions (the absence of oxygen), oxidizable organic matter, anaerobic microorganisms, and suitable electron acceptors. These are all required for a wetland soil to reduce, and absence of any one of these will therefore prevent reduction. It is thus quite possible for soils to be saturated with water, but not to undergo reduction because one or more of these prerequisites is missing.

Reducing conditions

Reducing conditions can be calculated theoretically for wetland soils by considering the following equation:

$$m \text{ (oxidant)} + m \text{ H}^+ + n \text{ e}^- = m \text{ (reductant)} \quad (2)$$

And through the Nernst equation:

$$Eh = E^\circ - \left(\frac{0.059}{n} \right) \log \left(\frac{\text{Reductant}}{\text{Oxidant}} \right) - 0.059 \left(\frac{m}{n} \right) \text{ pH}. \quad (3)$$

where: Eh = Electrode potential (Volt); E° = Standard electrode potential (Volt); m = Number of protons involved in the reaction; n = Number of electrons involved in the reaction.

Eq. (3) can essentially be reduced to:

$$\text{rH} = \frac{Eh}{29} + 2 \text{ pH}, \quad (4)$$

where, rH = Negative logarithm of hydrogen partial pressure; Eh = Electrode potential (Volt).

In soils, the rH would range from 20.78 in extremely oxidizing conditions to 0 in strongly reducing conditions. When the $\text{rH} < 20$, there is almost no molecular oxygen present in the soil environment and it is thus interpreted as signifying a reducing environment.

The presence and stability of the various oxidized and reduced species possible in wetland soils are given by pH/ Eh stability diagrams (Bohn et al., 2002), but is not elaborated on here.

Morphology

Iron and manganese ions are present in the reduced form as silicate minerals in rock and as such are fairly colorless. With chemical weathering, these iron and manganese ions are segregated, oxidized and impart a bright brown, yellow, red and or black colors to the soil. The iron and manganese minerals that form through these chemical weathering processes are immobile in oxidized soils. The iron minerals are predominantly hematite and goethite, with pyrolusite as the dominant manganese mineral. In wetland soils, the oxidized iron and manganese ions are reduced and become soluble and thus mobile, and largely lose their color. These properties of iron and manganese, i.e., brightly colored and immobile in the oxidized state and colorless and mobile in the reduced state, give rise to the unique color patterns that are observed in wetland soils.

Reduction, segregation, and relocation of iron and manganese in wetland soils give rise to redoximorphic features in the form of redox concentrations, redox depletions, and or reduced matrices (Richardson and Vepraskas, 2000; Schoeneberger et al., 2012). Redox concentrations (also known as an oximorphic color pattern) refer to brightly colored (Munsell chroma > 2) accumulations of oxidized iron and manganese to form masses (also known as mottles), pore linings, and or nodules and concretions. Redox depletions (also known as a reductimorphic color pattern) refer to zones where iron and manganese have been reduced and removed forming reduced (grey color with Munsell chroma ≤ 2) pore linings, depleted (grey color with Munsell chroma ≤ 2) and or reduced (with bluish or greenish colors, also known as grey colors) soil matrices. Soil matrix refers to the solid phase constituents of the soil (Fig. 1).

The color patterns that develop through the processes described above can be related to the soil water regime (Vasilas et al., 2010; Vepraskas, 2004). These different color patterns have found application in the WRB stagnic color pattern (Fig. 2) and gleyic color pattern (Fig. 3), and in the USDA definition of hydric soils. A stagnic color pattern is defined as one where the macro pores have a reductimorphic (grey) color, while the soil matrix has an oximorphic (bright) color. The converse is true for a gleyic color pattern: the macro pores have an oximorphic (bright) color, while the matrix has a reductimorphic (grey) color. Stagnic color patterns are associated with shorter periods of water saturation, where water primarily enters the soil from the soil surface along macro pores and cracks, while gleyic color patterns are associated with long periods of water saturation, where the water primarily enters the soil through ground water saturation (from the bottom upwards).

Oximorphic mottles are bright and vary from black to red to brown and yellow-orange that form when reduced iron and or manganese encounter oxygenated zones, are oxidized and then precipitate as iron and or manganese oxides. These precipitates typically coat soil structural units, pores, or root channels where oxygen can readily enter the soil. Reductimorphic mottles are grey (with a Munsell color chroma ≤ 2) that develop where iron and or manganese oxides are reduced and removed to reveal the grey underlying silicate minerals.

Fig. 1 Formation of a stagnic color pattern through water saturation in the macro (inter-ped) pores, where oxidized iron (Fe^{3+}) is reduced to Fe^{2+} , forming grey reductomorphic colors and is then relocated (as Fe^{2+}) into the oxidized matrix where it precipitates as Fe^{3+} oxides, forming bright, oximorphic colors.

The extent of gleying and mottle abundance, size, and color depends on the extent of reduction, which is governed by the hydrology and microbial activity. The microbial activity is, in turn, governed by the presence of readily oxidizable organic matter, microorganism species, and temperature (there is little microbial activity if the soil is too cold). Redoximorphic features can remain visible even after wetlands have been drained and thus offer a useful tool in determining the original wetland extent. With increasing wetness, organic matter accumulation, gley colors (chroma <1), as well as nodule and concretion occurrences are expected to increase (Vepraskas and Craft, 2016).

Exceptions can occur when red mottles are masked in soils with a much redder matrix that have formed, for example, from red glacial till parent material. Similarly, it is almost impossible for grey mottles to develop in a grey soil that formed from grey quartzitic parent material. In these cases soils will not exhibit an oximorphic or reductomorphic color despite experiencing water saturation and anaerobic conditions. Other wetland indicators such as measurements of water levels and or the presence of hydrophytic vegetation should then be used in the identification of wetland soils. Redoximorphic features can remain visible even after wetlands have been drained and thus offer a useful tool in determining the original wetland extent.

Soils that experience extreme variations in redox potential, through changes in water saturation, tend to have a lower clay content. This typically occurs along the zones that experience the longest periods of water saturation, such as macropores, where the clay minerals are degraded from 2:1 to 1:1 clays to quartz. Brinkman (1970) described this process that leads to a texture gradient due to water saturation, as ferrollysis (Fig. 3). Ferrollysis is thought to occur when the ferrous iron (Fe^{2+}) concentration in the soil solution increases dramatically when the soil is subjected to reduction. Ferrous iron then replaces the basic cations on the exchange complex of clays, and may or may not be removed from the soil. With oxidation, the ferrous iron is oxidized and removed from the soluble phase and thus also from the exchange complex. Oxidation of ferrous iron also leads to an increase of hydrogen (H^+), and a concomitant decrease in pH. If the pH decreases far enough, the clay minerals will disintegrate to release basic cations into the soil solution. Repeated oxidation–reduction cycles are required for ferrollysis to occur and would lead to a reduced pH and lowering of the overall clay content through clay destruction.

It is quite possible that the observed color patterns are not in phase with the current soil water regime because they might have developed under a previous period of water induced reduction, for example in drained wetlands. The following arguments can, however, be used to prove or disprove the contemporary nature of the observed soil morphology:

Gradient: First, one would anticipate a wetness and thus morphological gradient in topography. Indicators of water saturation are assumed to increase down slope. Second, a gradient in wetness and morphology is expected from the soil's surface to deeper in the profile. Last, a gradient should be observable within the peds as a logical sequence of the juxtaposition of colors (e.g., black—red—yellow—grey), as depicted for example in Figs. 1 and 2.

Fig. 2 Formation of a gleyic color pattern through the precipitation of reduced iron (Fe^{2+}) on the oxidized macro (inter-ped) pores as iron (Fe^{3+}) oxides, forming bright, oximorphic colors. The Fe^{2+} is formed through reduction in the reduced matrix, from where it moves under a concentration gradient to the oxidized ped face.

Fig. 3 Schematic representation of the ferrollysis process occurring in soils subjected to alternating oxidized and reduced conditions. Adapted from Brinkman, 1970.

Mottles: Actively forming mottles typically have diffuse boundaries, while relict mottles have more abrupt ones. This is because the former has an accumulation of iron and manganese that does not always move to the same area, while degradation is more probable in the latter, removing iron and manganese from the outside of the mottle inwards. It is also assumed that mottles would have greater accumulations of iron and manganese at the bottom of the mottle, rather than at the top because water saturation is expected to occur from the bottom upwards in the soil. In addition, mottle abundance is expected to increase with depth where water is actively saturating soils.

Juxtaposition: The sequencing of colors (juxtaposition) expected in actively saturated soils are normally black—red—yellow—grey, either from the inside out or from the outside in along a ped face (Figs. 1 and 2), reflecting the dominance of pyrolusite, hematite, goethite, and quartz respectively, as governed by the oxidation and reduction sequence (Table 3).

Nodules and concretions: Although nodules and concretions can actively form in contemporary saturated soils, they are not considered indicators of wetland hydrology because they are indurated and tend to persist within the soil and in the landscape. It is therefore possible for nodules and concretions to exist in both contemporary and relict saturated soils. [Nodules and concretions are

both hard, cemented concentrations of iron or manganese oxides. Concretions have an internal symmetry organized around a point, line, or plane, while nodules have no orderly internal organization.]

Conclusion: All the indicators discussed above are not necessarily present in all actively saturated soils. However, the more that these indicators occur, the more likely it would be that a soil experiences active water saturation and reduction and that the observed soil morphology is therefore not relict.

Hydric soils

The United States Army Corps of Engineers' Wetlands Delineation Manual (Environmental Laboratory, 1987) define wetlands as "Those areas that are inundated or saturated by surface or ground water at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas." Wetlands are therefore identified by the presence of hydrophytic vegetation, hydric soils, and wetland hydrology. At least one positive indicator from each of these parameters must be present to warrant the identification of a wetland. Hydrophytic vegetation is defined as vegetative species that are adapted to growth in saturated soil conditions. Hydric soils are those that have reducing soil conditions. Wetland hydrology requires that the area is permanently or periodically inundated with mean water depths <2.0 m, or that the soil is saturated with water to the surface for some time during the prevalent vegetation's growing season.

The USDA-NRCS [United States Department of Agriculture, Natural Resources Conservation Service] (2018) defines hydric soils (Table 4) as soils that are "saturated, flooded, or ponded long enough during the growing season to develop anaerobic conditions in the upper part of the soil." For identification, the hydric soils are divided into organic and mineral soils. Organic hydric soils are characterized by a thick organic layer that has accumulated over time because the microbial oxidation of plant residue is severely hindered under saturated conditions. The organic matter content in organic soils has to be greater than 20% and the soil must be at least 0.6 m to more than 9 m deep. Organic soils typically develop in areas where anaerobic conditions prevail (e.g., in depressions, bogs or marshes). Based on the nature of the accumulated organic matter, organic soils can be further divided into mucks (saprist or WRB Sapric qualifier), peats (fibrist or WRB Fibric qualifier), and hemists (mucky peat, peaty muck or WRB Hemic qualifier) as follows: Rub the wet soil material gently between the forefinger and thumb. If the material feels gritty after the first or second rub, then it is mineral soil material. If the material feels greasy after the second rub, then it is either mucky mineral or organic soil material. Rub the soil material gently two or three more times. If it now feels gritty or plastic, then it is mucky mineral soil material, and if it still feels greasy, then it is organic soil material. With the large organic matter content of organic soils, the bulk density is much lower ($0.9\text{--}1.2\text{ Mg m}^{-3}$) and they also have a much larger water holding capacity than mineral soils.

Mineral hydric soils have less than 20% organic material (based on the dry weight) and have visual redoximorphic features. These redoximorphic features can vary from very dark grey to very light (low chroma ≤ 2) matrix colors, with or without mottles. Mottles can either be zones of iron and or manganese oxide accumulation (oximorphic color pattern) or zones of iron and or manganese oxide depletion (reductimorphic color pattern). Mineral hydric soils form where moving or stagnating water accumulates, permanently or periodically, and are therefore typically found in low-lying positions, depressions, or on slopes where groundwater seeps out (Fig. 1). These soils can receive water through surface runoff or from groundwater seepage, and may have a subsoil layer that restricts water percolation (e.g., fragipan, clay pan, hardpan or bedrock) (Fig. 4).

Table 4 Summarized criteria for hydric soils (USDA-NRCS [United States Department of Agriculture, Natural Resources Conservation Service], 2018, [with approximate IUSS Working Group WRB (2015) equivalent classification in brackets]).

All Histels [Cryic Histosols] except Folistels [Folic Histosols]; or all Histosols [Histosols] except Folists [Folic Histosols]; or Soils in Aquic suborders [Stagnic or Gleyic qualifiers], great groups [Stagnosols & Gleysols], or subgroups, Albolls suborder [Stagnic or Gleyic Chernozems, Kastanozems, Phaeozems or Umbrisols], Historthels great group [Histic Cryosols], Histoturbels great group [Turbic Histic Cryosols], or Andic [Andic qualifier], Cumulic [cf Hyperhumic qualifier], Pachic [Pachic qualifier], or Vitrandic [Vitric qualifier] subgroups that:
a. Based on the range of characteristics for the soil series, will at least in part meet one or more field Indicators of Hydric Soils, or
b. Show evidence that the soil meets the definition of a hydric soil; or
Soils that are frequently ^a ponded for long durations ^b or very long durations ^c during the growing season ^d that:
a. Based on the range of characteristics for the soil series, will at least in part meet one or more field Indicators of Hydric Soils, or
b. Show evidence that the soil meets the definition of a hydric soil; or
Map unit components that are frequently ^a flooded for long durations ^b or very long durations ^c during the growing season ^d that:
a. Based on the range of characteristics for the soil series, will at least in part meet one or more field Indicators of Hydric Soils, or
b. Show evidence that the soils meet the definition of a hydric soil.

From: https://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/use/hydric/?cid=nrcs142p2_053959

^aFrequently is flooding, ponding, or saturation that is likely to occur often under usual weather conditions (>50% chance in any year, or more than 50 times in 100 years).

^bLong duration is a single event lasting from 7 to 30 days.

^cVery long duration is a single event lasting longer than 30 days.

^dGrowing season is the portion of the year when soil temperatures are above biologic zero (5 °C) at 50 cm.

Fig. 4 Soil properties along a wetland-to-upland gradient. Note that the seasonal high-water table, indicated by the mottled zone, occurs at increasingly shallower depths and only reaches the surface at the lower elevations. Adapted from [Tiner and Burke \(1995\)](#).

Measurement

The prevalent conditions in the root environment of wetland soils can be described qualitatively as ‘anaerobic’, ‘reduced’, ‘flooded’, ‘saturated’, or ‘waterlogged’. Wetlands are also defined rather qualitatively based on the presence of hydrophytic vegetation, hydric soils, and wetland hydrology. However, measurements of water table position, redox potential, pH, and reduced iron (Fe^{2+}) need to be made to define and characterize wetlands quantitatively.

Hydrology

Water content measurements are probably the most direct approach to ascertain soil water saturation. This can be done through water level measurements in piezometers or in wells or by measuring the soil water content with a neutron water meter, tensiometer, time domain reflectometry (TDR) or other similar technology. Water level measurements in piezometers or wells are typically expressed as hydroperiod, seasonal high water level, or the duration of water saturation within a specific horizon. Hydroperiod is, however, more typically modelled from precipitation, temperature, and evapotranspiration. In the case of soil water content measurements, these need to be converted to degree of saturation (water volume as a fraction of the pore volume that is in turn calculated from the bulk density) in order to estimate water saturation in the soil or at a specific depth. Irrespective of the method used to determine soil water saturation, it should be longer than 7 days during the growing season—i.e., when soil temperatures $>5^\circ\text{C}$ at 50 cm. It has also been noted that soils can be reduced if the water saturation reaches 70% of porosity ([Van Huyssteen et al., 2004](#)).

Redox potential and pH

It is quite difficult to measure oxygen concentration and the rate of oxygen diffusion in wetland soils. Measuring the soil Eh is, however, a viable alternative in the laboratory and in the field. Soil Eh varies from -300 to $+700$ mV in flooded soils and is $< +350$ mV in permanently waterlogged soils, compared to $> +400$ mV in aerated soils. The Eh must, however, be measured in conjunction with pH to characterize fully the wetland biogeochemical environment (see the discussion on reducing conditions).

Redox potential measurements are done by installing platinum electrodes to the desired soil depths. These electrodes are then linked to a volt meter and a standard calomel reference electrode. The pH measurements are done similarly, but with a pH electrode instead of the platinum one. Soils are considered reduced when the rH < 20 .

In situ redox potential and pH measurements, however, suffer from quite a few limitations. First, the redox couples are not necessarily in equilibrium with their soil environment, except in highly reduced soils because the soil system is very heterogeneous and considerable differences can occur over short distances (less than millimeter scale). Second, respiration is actively taking place in all soil environments and electrons are therefore being added and removed continuously, and thus equilibrium is seldom, if ever, reached. Third, redox potential measurements cannot be interpreted on their own because they are interrelated with the pH, necessitating both Eh and pH measurements. Last, the surface of the platinum electrode can be contaminated through the precipitation of oxide coatings, sulfides and/or other impurities, especially in in situ installations.

Indicators

As discussed above, the direct measurement of reduction in soils is time consuming, tedious, and suffers from equipment issues. Furthermore, characterization of redox potential must be done by measuring Eh and pH, which are then evaluated against Eh-pH stability diagrams. Taking only a single measurement would also not reflect the annual or inter-annual variation. Various indicators can, however, be used to determine the presence of reduced elements in the soil.

Indicators, such as α , α' dipyridyl, can be used to test for the presence of reduced ions (Childs, 1981), such as Fe^{2+} in this case. These indicators are quick and easy to use, but might be difficult to obtain, are hazardous to use, and also only provide a snapshot in time.

Indicator of Reduction In Soil (IRIS) tubes (Castenson and Rabenhorst, 2006) are PVC tubes covered with synthetic ferrihydrite, goethite and hematite, installed vertically into the upper 50 cm of soil for a period of 2–4 weeks. In a reduced soil more than 30% of the ferrihydrite paint is removed from the IRIS tube. These tubes therefore offer an innovative, cheap and easy method to determine temporal soil reduction. See for example Rabenhorst (2012), Mutiti et al. (2018) and LeFevre et al. (2021).

Conclusions

Wetland soils are unique environments that occur at the interface between aquatic and terrestrial ecosystems. Traditionally, humans have a rather pessimistic relationship with wetlands, as depicted in terms such as 'bogged down', 'swamped' and 'quagmire'. It is therefore no surprise that wetlands have been drained and filled in to 'improve' the land. The net effect has been that the hidden ecosystem services of wetlands such as provisioning, regulating, cultural, and supporting services, were overlooked. Fortunately, this trend has recently been reversed and wetlands now occupy an increasingly important position on local, national and global agendas.

Wetlands are predominantly classified based on their relationship to water bodies. It is, however, only the terrestrial wetlands such as marsh and peatland or the estuarine and palustrine wetlands where the soils occur at the interface between oxidizing (aerobic) and reducing (anaerobic) environments. It is these alternating conditions that cause the unique soil morphology that is used for wetland identification and delineation.

In aerobic soil environments the microorganisms utilize oxygen as electron acceptors in the oxidation of organic matter to obtain energy. However, in anaerobic environments the microorganisms must utilize other electron acceptors such as nitrate, manganese, and iron that result in them obtaining increasingly less energy. These reactions cause a reducing environment (lowering of the electrode potential), which causes the manganese and iron coloring agents to be reduced, become soluble, and lead to the development of different oximorphic and reductimorphic color patterns. It is these color patterns that have been used to define stagnant and gleyic color patterns and hydric soils. These redox color patterns find application in various soil classification systems and in wetland identification and delineation.

Abstract

Rice is a very important crop for human nutrition globally, and most rice soils and their processes are exceptional because they are flooded for a considerable part of the year. The rice production system underwent big changes following the Green Revolution, with much greater irrigated areas, more crops grown per year, and the increasing use of agro-chemicals to achieve much higher yields. This article describes the major cropping environments, outlines the distribution and main characteristics of “paddy soils”, presents the basics and advances of soil fertility and nutrient management, and discusses important sustainability problems of rice soils and cropping systems.

Key points

- Rice soils cover more than 160×10^6 ha and are mostly located in the tropics and sub-tropics around the world.
- Their particular characteristics are due to flooding for part of the year, both in irrigated and rainfed cropping systems.
- Flooding of paddy soils has marked effects on electrochemical, chemical and microbial processes, which affect nutrient availability and soil organic matter decomposition.
- The quality of rice soils can be maintained even where rice is continuously grown in monocropping at high production levels.
- Problems of rice soils and systems include water shortages, excessive N application and losses to the environment, and considerable methane emissions.

Introduction

Wetland rice or paddy soils provide the staple diet for nearly half the world's population. Worldwide, the total harvested rice area covers about 164 million ha, and about 85% of the rice area is situated in Asia, with a similar contribution to rice production. The flooded soil environment is one of the specific characteristics associated with rice cultivation in the traditional rice-growing areas in the river deltas of China, Southeast Asia and the Indian subcontinent (Moormann and van Breemen, 1978). The term “paddy soil” does not describe a specific soil type but rather denotes soils in lowland rice production systems having a prolonged period of submergence. Water regime is used to classify the environments of paddy soils into broad ecosystems, distinguishing irrigated and rainfed rice grown predominantly in the lowlands, upland rice grown in the uplands under aerated soil conditions, and deep-water rice in flood-prone river deltas and coastal areas. Paddy soils need to be discussed in the context of their production systems, considering trends, opportunities and challenges, and here we focus on lowland rice production systems of Asia, because of their prominent role in global food security, and in forcing global climate change by the production and release of greenhouse gasses.

Cropping environments in Asia's lowlands

With an increasing demand for rice from a growing population, rice cropping and paddy soil management in Asia underwent substantial intensification since the first modern high-yielding varieties with shorter growth periods, reduced height and better

fertilizer response were released in the early 1960s. Rice production tripled from 1948 to 1990 because of a larger physical land area cropped to rice, an increased number of crops grown per year, and greater yields as a result of Green Revolution technologies, such as improved germplasm, irrigation infrastructure, water and pest management, and increased use of inorganic fertilizer (GRiSP (Global Rice Science Partnership), 2013). The intensification was accompanied by changes in chemical, biological and physical processes in the soil-floodwater system. The duration of soil submergence and tillage operations increased, especially in the expanding double- and triple-rice cropping systems. In such systems, the periods of aerobic soil conditions are shorter and mostly restricted to dry fallows. The duration of the dry fallow period between two rice crops varies from a few weeks up to two or three months in the typical annual double-rice cropping system in Asia.

In the mid-1990s, the harvested area in Asian rice ecosystems included 73×10^6 ha of irrigated rice, 46×10^6 ha of rainfed lowland production, 9×10^6 ha of upland rice, and around 4×10^6 ha of flood-prone rice ecosystems (Huke and Huke, 1997). Although the overall physical rice area was expected to change only little in the future, the forecast (Rosegrant et al., 1995) was that total rice production in Asia would have to increase by about 25% from 530×10^6 t in 1999 to 662×10^6 t in 2020 to meet the increasing rice demand in Asia (Table 1). This forecast was generally met, with total paddy production in Asia reaching 676×10^6 t in 2020. However, contrary to the forecast, this goal was achieved by a considerable increase of the harvested area of rice to 141×10^6 ha whereas the average rice yield remained below the target of 4.9 t ha^{-1} (Table 1), only reaching 4.8 t ha^{-1} in 2020. The ongoing changes in rice demand, environment and socio-economic conditions, and their effects on productivity and management of paddy soils in Asia's intensive rice systems are depicted in Fig. 1. Most of further production increase will have to come from grain yield increases in the lowland rice ecosystems, and technologies developed in recent years provide substantial opportunities for farmers to increase productivity and profitability as rice demand continues to increase. With sufficient investment, rice production can undergo an intensification that is environmentally sound and sustains the soil resource base. However, in some areas, crop management may need to change in response to environmental concerns, resource availability or low profitability, with possible adverse effects on rice yields and soils.

Distribution and important characteristics of paddy soils

Paddy soils constitute an important group within the wetland soils where water saturation dominates soil development and the types of plant and animal communities (IRRI, 1978). Thus, paddy soils are defined as wetland soils with standing water in banded (Plate 1) and leveled fields (Plate 2) used for cultivation of rice (bunds are small dikes around the field to keep the water from running off). Paddy soils may support an upland, non-rice crop in the dry season when soils are aerated, but insufficient drainage capacities often make rice the only possible crop choice in the lowlands of the humid tropics. Free surface water may occur naturally or rainfall, runoff or irrigation water may be retained by field bunds or compacted subsoil layers.

According to the FAO World Reference Base for Soil Resources (IUSS Working Group, 2015), most paddy soils are designated as Anthrosols (having a puddled surface layer and a plow pan) or as Gleysols, Fluvisols, Planosols, Plinthosols and Histosols. Smaller areas of paddy soils fall within the gleyic soil units of Arenosols, Andosols, Cambisols, Solonetz, Solonchaks, Luvisols, Lixisols, Acrisols and Alisols. Although Vertisols, Nitisols and Ferralsols have no gleyic soil units, these soils may be artificially flooded and used for rice cultivation. The U.S. Department of Agriculture Soil Taxonomy does not recognize wetland soils at the level of soil orders, but classifies soils with aquic conditions at the suborder level and soils with hydromorphism at the subgroup level (USDA, 1999). Most paddy soils are therefore assigned to the aquic suborders of Andosols, Oxisols, Vertisols, Ultisols, Mollisols, Alfisols, Inceptisols and Entisols. A global assessment of rice soil quality and constraints was conducted by Haefele et al. (2014).

Natural or artificial flooding of paddy soils has marked effects on electrochemical, chemical and microbial processes, which in turn affect soil fertility and thereby crop growth in a dynamic manner. The main electrochemical changes include a decrease in redox potential and changes in soil and solution pH, microbially mediated processes which are mainly controlled by organic matter and reducible Fe contents of the soil (Kirk, 2004). With decreasing redox potential, oxidized forms of soil redox systems serve as electron

Table 1 Yield, area and production of irrigated and non-irrigated rice for Asia in 1999, and required changes in yield based on projected changes in area and production requirements until 2020 (Dawe, IRRI, unpublished).

System	Grain yield			Area			Production		
	(t ha^{-1})		$\Delta\%$	(10^6 ha)		$\Delta\%$	(10^6 t)		$\Delta\%$

Projected changes in area and production are based on Rosegrant MW, Sombilla MA, Perez N (1995) *Global Food Projections to 2020: Implications for Investment. Food, Agriculture and the Environment*. Discussion Paper No. 5. International Food Policy Research Institute: Washington, DC. pp. 1–54.

Fig. 1 Expected changes in rice demand, environment and socio-economic conditions affecting the productivity and management of paddy soils in intensive rice systems in Asia. Some of these changes have already occurred or are in progress in certain areas.

Plate 1 Flooded rice fields at transplanting (Bangladesh, 2005).

Plate 2 Transplanted rice in the field with standing water (Bangladesh, 2005).

acceptors in microbial respiration. The general sequence of reduction is O_2 - NO_3^- - $Mn(III,IV)$ - $Fe(III)$ - SO_4^{2-} - CO_2 - H^+ . Some of these redox systems are overlapping (e.g., O_2 , NO_3^- and $Mn(III,IV)$), whereas others are not (e.g., O_2 and $Fe(III)$; SO_4^{2-} and CO_2). Reduction of CO_2 causes the emission of methane from flooded paddy soils in fresh- water systems. The electrochemical changes induce a pH increase in most acid soils, whereas the pH decrease upon flooding of calcareous and sodic soils is due to the accumulation of carbon dioxide. Two distinctly different topsoil layers develop: a thin aerobic surface layer with a depth of few millimeters caused by O_2 diffusion through the aerobic flood-water layer (and around the rice root surface due to O_2 transport through the rice plant's aerenchyma) and the anaerobic soil layer below with a variable depth. Most roots are concentrated in the first 20 or 30 cm below the soil surface (Kyuma, 2004). The presence of aerobic and anaerobic soil compartments causes considerable soil N losses through mineralization-nitrification-denitrification reactions (Fig. 2). In most soils, flooding increases the plant availability of P, K, Ca, Mg, Na, Mn, Fe and Si, at least temporarily. Reduction of Fe and Mn-oxides releases sorbed and occluded elements such as P, Zn, Cu, B and Mo. Increasing pH reduces plant availability of Zn and Cu, whereas the solubility of Mo increases. Reduction of SO_4^{2-} reduces plant-available S but SO_4^{2-} is a common accompanying anion in commercial mineral fertilizers.

A widespread and traditional soil preparation practice in lowland production systems is puddling (Plate 3). Puddling refers to the practice of mixing surface soil with water to make it soft and leveled for transplanting, the traditional crop establishment method for rice. Other short-term puddling effects are the destruction of soil aggregates, irrigation water savings due to reduced percolation, reduced soil bulk density, increased soil water-holding capacity, decreased hydraulic conductivity, an acceleration of the electro-chemical processes described above, and good weed control. A long-term effect of puddling is the development of a hardpan (plow pan, traffic pan) in the subsoil below the puddled layer, often associated with the accumulation of Fe, Mn and Si (Kawaguchi and Kyuma, 1977). The puddled surface layer is often characterized by a coarser texture caused by clay mineral decomposition or transport processes. Hardpan formation may take from three to 200 years, depending on soil type, climate, hydrology and puddling frequency.

Paddy soil fertility and nutrient management

The nutrient-supplying capacity of paddy soils in the traditional rice-growing environments was largely determined by their parent material, and the alluvial deposits in the river deltas and flood plains. Natural nutrient inputs derived from sedimentation, irrigation and rainwater, organic residues or manure, biological N_2 -fixation, and carbon assimilation by floodwater flora and fauna (Greenland, 1997). Efforts to maintain soil fertility have historically centered around maintaining soil organic matter (SOM) through the addition of green manure, animal waste and crop residues, but their significance has declined continuously in the last decades (Dawe et al., 2003). The total annual C input in a double-rice cropping system may currently range from 4000 to 7000 kg C ha^{-1} , including inputs of 1000–2000 kg C ha^{-1} from the photosynthetic and heterotrophic biomass in rice fields. Despite high

Fig. 2 Aerobic and anaerobic soil compartments in a flooded paddy soil, and related sulfur and nitrogen dynamics. Redrawn from Greenland DJ (1997) *The Sustainability of Rice Farming*. International Rice Research Institute (IRRI) and CABI Publishing: Manila/Wallingford. pp. 1–273.

Plate 3 Flooded rice fields after puddling (Bangladesh, 2005).

temperatures in the tropical soil floodwater environment and rapid initial breakdown of organic inputs, average SOM concentrations in paddy soils are higher than in aerated soils, mostly because of high organic matter inputs and a slower (anaerobic) decomposition rate of humus. The typical soil for irrigated lowland rice maintains an average carbon concentration of about 1.5–2% and a nitrogen concentration of about 0.15–0.2%; paddy soils are possibly an exception to the rule that the shift from natural vegetation to arable use always causes a large loss of soil organic carbon. Crop intensification with prolonged soil flooding changes the nature of SOM towards more aromatic compounds (chemical structures with six C-atoms arranged in a ring) because of changes in the breakdown of organic matter under increasingly anaerobic conditions. These changes appear to have limited effects on yield stability under rice monocropping, but were hypothesized to affect systems with intensive triple cropping and nearly continuous soil submergence (Kirk and Olk, 2000). However, an analysis of yield trends in long-term experiments with intensive rice-based cropping systems in tropical and subtropical regions of Asia suggested that yields in most experiments have remained stable with recommended fertilizer N, P and K addition (Dawe et al., 2000). There is also evidence that organic matter application did not improve grain yield trends in rice-based systems vis-à-vis a balanced mineral fertilizer application. But the application of organic matter is often profitable if used as a nutrient source complementary to inorganic fertilizer, also in part because of the recycling of often deficient micronutrients.

A unique contribution to the indigenous N supply of paddy soils derives from biological N_2 -fixation (BNF), providing 15–50 kg N ha⁻¹ per cropping cycle from blue-green algae in the floodwater and heterotrophic bacteria in the rice rhizosphere. The mineralization of algae and bacteria provides a constant supply of ammonium (NH₄⁺), the dominating inorganic-N form available to plants under anaerobic soil conditions. Because of efficient plant uptake of mineralized N, larger amounts of extractable NH₄⁺ are found only after soil flooding during the initial decomposition of residues or if fertilizer-N is applied (Fig. 3). The major N-loss mechanism during the cropping season is ammonia (NH₃) volatilization from the flooded soil, particularly when NH₄⁺ concentrations in the floodwater rise after N-fertilizer application. Nitrogen is also leached, denitrified or immobilized by soil microbial biomass and SOM. About 70% of the fertilizer-N applied by farmers is currently not recovered by crop N uptake, but N-recovery efficiencies of applied fertilizers can reach 50% or more in farmers' fields with adequate real-time N-management strategies (Dobermann et al., 2004). Considerable amounts of nitrate only accumulate in the aerated soil during fallow periods or during upland cropping cycles in rice-based rotations. Almost all nitrate is lost after soil flooding because of leaching and denitrification. Including upland crops in rice-based systems affects mineralization, plant availability and loss of inorganic-N. Soil aeration also accelerates the turnover of SOM and changes its composition towards a less aromatic nature, with possible adverse effects on the amount of indigenous soil-N supplied to rice. However, few long-term data are available from experiments

Fig. 3 Nitrate (NO₃⁻) and ammonium (NH₄⁺) dynamics in a rice-rice and a maize-rice cropping experiment with and without fertilizer N application, IRRI experimental farm, 1995. Fertilizer N was applied in several split applications with a total of 190 kg N ha⁻¹ in the dry season (January to mid-April) and 100 kg N ha⁻¹ in the wet season (mid-June to early October). F = flooding; N = fertilizer N split application.

that directly compare crop rotations but declining soil organic carbon concentrations were repeatedly reported from systems combining rice with upland crops. Other anticipated future changes in crop management include mechanization of soil preparation and harvest operations, changes in water management towards increasing soil aeration (see below), and larger amounts of crop residues remaining in the field for farmers to deal with (Fig. 1). These changes will affect soil C and N cycling in paddy soils, and research currently aims to develop a portfolio of technology and management options to mitigate potential adverse effects (Ladha et al., 2003).

Rice requires an adequate supply of nutrients from various sources to produce high and sustainable yields. A rice crop with a yield of 6 t ha⁻¹, for example, accumulates about 100 kg N, 18 kg P, 100 kg K, 0.3 kg Zn, 11 kg S, 480 kg Si, 21 kg Mg, 24 kg Ca, 3 kg Fe and less than 0.1 kg Cu and B. Without fertilizer, the indigenous supply of N limits yield in most paddy soils. Other nutrients, which have to be commonly supplied with fertilizer in intensive rice systems, include P and K, and in some areas also S or Zn. Required fertilizer rates are determined by the deficit between plant nutrient requirement and indigenous nutrient supply (Dobermann et al., 2004). This is particularly relevant for N, because residual effects of fertilizer-N application are small and long-term trends show little change in the indigenous supply of N with time in farmers' fields. For nutrients other than N, fertilizer application is often recommended even in the absence of a yield response (maintenance rates) to avoid depletion of soil nutrients particularly at elevated yield levels when nutrient removal with grain and straw is large. However, a comparison of current fertilizer rates used by farmers in seven major irrigated rice areas in Asia showed that fertilizer use is often not in congruence with the deficit between yield level and indigenous supply of nutrients (Table 2). On average, farmers used 90–140 kg N, 10–25 kg P and 10–55 kg K ha⁻¹ to achieve grain yields of 4.4–6.2 t ha⁻¹ in the typical annual double- or triple-rice cropping systems of South and Southeast Asia. This is about 50–75% of the climate-adjusted, genetic yield potential of 8.3 t ha⁻¹ that has been estimated for existing germplasm across sites, seasons and years. In general, yields and fertilizer rates are larger in the typical dry season with greater solar radiation than in the typical wet season with greater cloud cover. The indigenous supply of N, P and K in irrigated rice in Asia was on average 41–65 kg N ha⁻¹, 12–19 kg P ha⁻¹ and 61–102 kg K ha⁻¹, but varied widely with site, year, season, farm and field. In rainfed lowlands, yields and fertilizer applications are generally smaller, decreasing from favorable to unfavorable lowlands with increasing production risk.

Blanket fertilizer recommendations still prevail in most of Asia's lowland rice areas without considering amount and spatial distribution of indigenous nutrient supplies. There is also concern that fertilizer-rates of P and K are not optimally adjusted to long-term needs. A typical input-output balance for P and K in farmers' fields is given in Table 3. On-farm measurements in irrigated rice have confirmed for a wide range of soils and growing environments that farmers generate slightly positive P balances with current fertilizer P management, whereas their fertilizer-K application is insufficient to balance K removal in grain and straw. Modern site-specific nutrient management (SSNM) strategies have been developed in recent years to manage nutrients more efficiently and supply fertilizers as required by the crop, considering indigenous supplies of nutrients (Dobermann and Fairhurst, 2000) and have been shown to be beneficial for smallholder farmers (Chivenge et al., 2021). Estimates of indigenous supplies of nutrients need to be verified if general crop management of paddy soils changes (see Fig. 1). Changes in fallow period and residue management or system diversification are likely to introduce changes in indigenous supplies that are sufficiently large to require fertilizer adjustments.

Deficiency of Zn is the most widespread micronutrient disorder in rice, not only on soils with a traditionally small supply of Zn (e.g., neutral and calcareous soils containing a large amount of bicarbonate), but increasingly also on other soils under intensive rice cropping (Dobermann and Fairhurst, 2000). Sulfur deficiency occurs mainly in upland soils containing allophane (an aluminosilicate with primarily short-range structural order, which occurs as exceedingly small spherical particle especially in soils formed from volcanic ash), soils low in organic matter, highly weathered soils containing large amounts of Fe oxides, and sandy soils with high percolation. Lowland rice areas with common S deficiencies are located in Bangladesh, China, India, Myanmar, Pakistan, Sri Lanka and Thailand. Other nutrient disorders are usually only of local importance.

Table 2 Average seasonal indigenous N, P and K supply, fertilizer use, and grain yield in intensive rice systems of South and Southeast Asia.

Lowland rice systems and declining water availability

Today, nearly 90% of the fresh water diverted for human use in Asia goes to agriculture and, of this, more than 50% is used to irrigate rice. With the growing demand for water for non-agricultural uses (domestic, municipal, industrial and environmental), the proportion available for agriculture is projected to decline from 90% to 73% in developing countries in the near future. Indicators of a looming water crisis include falling groundwater tables in regions where mainly tube wells are used for irrigation and severe water shortages downstream of some major rivers in Asia (e.g., Yellow River, Indus and Ganges). Fig. 4 gives the distribution of irrigated and rainfed lowland rice in Asia, and major ‘hot spots’ of groundwater depletion and reduced river water flows. The productivity of intensive rice systems depends strongly on the availability of sufficient irrigation water, and production is likely to decrease with water shortage unless suitable mitigation options are developed (Tuong and Bouman, 2003). By 2020, physical water scarcity was projected for wet-season irrigated rice in North China (2.5 million hectares), Pakistan (2.1 million hectares) and north and central India (8.4 million hectares), as well as on 2 million hectares of dry-season rice in central India.

Water productivity at the field level can be increased by (i) increasing yield per unit cumulative evapotranspiration through the use of high-yielding, short-duration varieties and optimal, site-specific agronomic practices, (ii) more effectively using rainwater by using dry-seeding rice technologies to synchronize the start of the cropping season with the start of the rainy season, and (iii) reducing unproductive water losses (seepage, percolation, evaporation) through adequate soil and water management. Examples of the latter include saturated soil culture (daily flooding with about 0.01 m water depth) or alternate wetting-and-drying regimes (flooding every 2–7 days with 0.02–0.05 m water depth). These measures frequently cause a reduction in yield and profitability, although they often result in an increased water productivity. A more radical approach is to grow rice under permanently aerobic soil conditions by keeping the soil water content in the root zone always at or below field capacity, a technology called aerobic rice. Contrary to upland rice, this system is intended to be a high-yielding system, but more research is required to evaluate long-term effects on soil organic matter and nutrient cycling. Such systems may gain local importance where water is limiting and prices for rice are high, but yields may not reach those achieved in well-managed flooded systems. The adoption of such water-saving irrigation technologies will cause a shift from mainly anaerobic soils to partly or even completely aerobic soils, but most research examining this issue and possible consequences is still inconclusive. Changes in the soil moisture regime of paddy soils will have profound effects on soil organic matter turnover, nutrient dynamics, carbon sequestration, soil productivity, weed ecology and greenhouse gas emissions in irrigated systems. Water-saving technologies must therefore develop into integrated natural resource management approaches to maintain the productivity, profitability and sustainability of the evolving systems.

Water productivity in rainfed lowland systems can be increased through more efficient and effective use of all inputs. A general increase in productivity will also reduce the pressure for more intensive management and area expansion of irrigated lands. Direct-seeding techniques offer further opportunities to achieve greater (water) productivity by timely crop establishment. Avoiding drought stabilizes yields and in some situations a second, upland crop can be grown after rice using the residual soil moisture content. Such crop intensification must be accompanied by balanced fertilizer application and adequate residue management on the often-poor-quality soils in rainfed systems to maintain or build up SOM and thereby the indigenous supply of nutrients.

Sustainability and environmental issues

In general, rice cultivation is sustainable, even where rice is continuously grown in monocropping at high levels of production (Greenland, 1997). The quality of the soil resource base can be maintained through adequate management practices, including proper crop residue and water management, tillage operations, soil aeration during fallows and balanced fertilizer application (Yanai et al., 2022). The sustainability of rice cropping may be at risk, however, where management-induced changes strongly influence soil characteristics and the soil environment. This may include prolonged soil submergence in intensive systems with three

Fig. 4 Current distribution of irrigated (A) and rainfed lowland rice (B) in Asia (based on Haefele SM, Nelson A, Hijmans RJ (2014) Soil quality and constraints in global rice production. *Geoderma* 235–236: 250–259.), and major ‘hot spots’ of groundwater depletion (squares with solid lines) and reduced river water flows (squares with broken lines).

rice crops per year as well as prolonged soil aeration because of crop diversification (Fig. 1). In the following, the focus is on selected issues that are of general importance for sustainable paddy soil management and the environmentally sound production of rice.

When crops are grown with irrigation in dry regions, the sustainability of agriculture is potentially threatened by several water-related processes, such as salinization and alkalization. In the semiarid tropics, irrigation may cause salinization of soils by rising saline groundwater tables. Alkalization can occur when irrigation water with a positive residual alkalinity is used. However, ample irrigation can leach salts from the topsoil through percolation if sufficient drainage is available. This even makes irrigated rice a reclamation crop for such soils. A very different water-related problem is accidental flooding caused by inadequate irrigation control in some parts of tropical Asia, taking valuable land out of agricultural production: for example, this accounts for about 6 million ha of arable land in India annually.

Other soils that pose problems for management in the lowlands include Thionic Fluvisols or acid sulfate soils, which are widespread in Thailand, Vietnam and Indonesia. Potential acid sulfate soils strongly acidify upon drainage, whereas actual acid sulfate soils are characterized by pH values around four. Rice cropping under submergence offers one of the few sustainable uses of these soils. Management strategies include (i) complete soil oxidation through drainage and leaching of acidity from the crop root zone, which offers a permanent solution but may cause a contamination of surface water affecting crops, soils and aquatic organisms in surrounding regions, or (ii) the limitation of soil oxidation by maintaining a permanent, high groundwater table, which requires sufficient irrigation water.

Environmental concern is increasing because the intensification of rice cropping in the past has led to an excessive use of fertilizer-N and pesticides in many intensive rice-growing areas in Asia. This has been recognized, and much progress has been made in recent years in developing and disseminating adequate management strategies, such as real-time N management and integrated pest management. Current changes in many cropping environments include a shift from irrigated transplanted rice to direct seeding and the use of water-saving technologies. This causes greater weed pressure and often leads to an increased use of herbicides, particularly at sites with further intensification and mechanization because of labor shortages. Research efforts aim to better integrate water, nutrient, weed and pest management approaches to enhance direct environmental and economic benefits for farmers.

Paddy soil environments have also caused global environmental concerns because methane (CH_4) is second in importance to CO_2 as a greenhouse gas and flooded paddy soils contribute about 10% of global CH_4 emissions (Wassmann et al., 2000). Although the CH_4 production of paddy soils is much smaller than originally assumed, it is still an important contribution. Methods to reduce this share include water-saving technologies as described above, improved crop residue management and direct seeding instead of transplanting. Care has to be taken to avoid significant increases in N_2O -emissions, another greenhouse gas which is ten times more “effective” than methane. Soil moisture regimes keeping the soil redox potential between -100 and $+200$ mV combined with efficient N fertilizer management could minimize both methane and nitrous oxide emissions.

Conclusions

Paddy soils are defined through their production environment, the typically irrigated and rainfed lowland rice cropping systems. Cropping intensification in the last 40 years has greatly increased rice yield and production, and further intensification is needed to achieve food security at the national and household level. Productivity increases at the farm level could be mainly achieved in two ways. One option is the continuing optimization of the existing rice-based cropping systems with two to three annual rice crops and short fallow periods. There is strong evidence that rice double cropping in Asia can provide high, sustainable yields despite an increase in the duration of soil submergence and a shift from organic to inorganic nutrient sources in the last 40 years. Sufficient inputs of external nutrients with fertilizer are necessary to match the insufficient supply of nutrients from indigenous sources, but inefficient fertilizer use, nutrient imbalances and excessive pesticide use have become widespread and must be overcome through more site- and season-specific crop, soil and water management to efficiently manage all inputs. The second option for farmers is to turn to crop diversification, adding more profitable non-rice crops to the rice-based cropping system or grow rice under aerobic soil conditions. Conditions imposed in the non-rice season will influence important characteristics of paddy soils and remove typical paddy soil characteristics temporarily or permanently. A key issue is whether the high productivity of current rice cropping systems can be sustained in such diversified systems. The other big uncertainty is how changing rain patterns will affect water availability or flooding patterns in many rice environments, which might soon change cropping systems and paddy soils in many regions of Asia and beyond.

Abstract

The chapter informs about the formation and the variety of soils from volcanic parent materials, their pathways of weathering, their processes of soil formation, and their most important properties. A special focus is given on the classification of soils of the Andosol/Andisol type developed from non-volcanic parent materials, as their formation is not yet fully understood.

Glossary

Allophane An aluminium(Al)-hydroxo-silicate of the clay fraction that cannot be identified by X-ray diffraction because of its amorphous or poorly crystalline structure (short-range-order minerals). Allophanes are common weathering products of volcanic ash, and are characterized by surface areas up to 1000 m² g⁻¹.

Alu-andic Andic properties mainly caused by Al-hydroxo-organic complexes.

Andic properties Soil properties characterized by short-range-order minerals and or metal–organic complexes as a result of the weathering of volcanic ejecta. Common features are large contents of soil organic matter throughout the profile, low bulk density, thixotropic behavior, high P-retention.

Andosol or Andisol Soils commonly developed from volcanic ejecta having an intermediate stage of soil development with andic properties characterized by short-range-order minerals and or metal–organic complexes. Andosols, however, may also develop from non-volcanic parent materials under specific site conditions.

Cryptopodzols Soils fulfilling all classification criteria of Podzols (spodic properties), but without visible eluvial and illuvial horizons.

Ferro-andic Andic properties mainly caused by Fe(iron)-hydroxo-organic complexes.

Imogolite An aluminium-hydroxo-silicate of the clay fraction with tubular structures commonly found in Andosols as weathering products of volcanic ejecta.

Sil-andic Andic properties caused by Si-hydroxo-organic complexes. The acid-oxalate extractable silica content should be 0.6% or more.

Spodic properties Soils (Podzols) characterized by very low pH values and leaching of metal–organic complexes and or oxidic Fe- and Al- compounds from topsoil to subsurface horizons commonly in coarse-textured parent materials under cool-humid climatic conditions (podzolization).

Thixotropic features Abrupt change of the viscosity of materials under shear stress. It may happen in soil material with andic properties.

Vitric Vitric soil properties represent an early stage of soil development between fresh pyroclastic deposits containing volcanic glass and andic properties.

Key points

- Soil formation on parent materials of volcanic origin in general
- Andosols or Andisols of volcanic origin
- Andosols and soil with andic properties on non-volcanic parent materials

Introduction

Molten **magma** extruded as liquid lava or ejected as cinders or ash from deep within the Earth adds to the variety of parent materials and soils we find on landscape surfaces. Unlike their plutonic counterparts that cool and solidify slowly underground and are subject to weathering after uplift and erosion, **volcanic rocks** cool and solidify immediately upon exposure to the atmosphere. The faster cooling results in the formation of amorphous/glassy and finer rock textures in volcanic rocks (Fig. 1). Plutonic and volcanic rocks with similar or different chemical composition will lead to the formation of different soils depending on time of soil development, i.e. age volcanic rock exposure, and site conditions. This is especially true for finely divided pyroclastic **ejecta** that cool even before deposition (Fig. 1). The porosity and texture of such cindery or ashy materials differ greatly from those of other parent materials, and vitric volcanic ash develops into soils with andic soil properties, i.e. the Andosol or **Andisol** type of soils.

In addition to rock texture and porosity, volcanic materials vary in chemical and mineral composition. The chemical composition of the magma determines, to a large extent, the texture and porosity of the extruded material. Vitric and porous pyroclastic rocks are more common in high-silica magma that forms acidic rocks than the less viscous, basic magma that erupts less explosively and produce basaltic lavas (Nockolds, 1954; Fig. 1).

The higher viscosity of silicic magma results in the formation of steep-sided, cone-shaped **volcanoes** exemplified by Mount Fuji-san in Japan, whereas the basic, low-viscosity magma forms broader, shield volcanoes exemplified by the volcanoes of the Galapagos Islands. Both types of volcanoes produce **pyroclastic materials** and lava, but the silicic magmas have more frequent explosive eruptions than shield volcanoes. The 1980 eruption of Mount St. Helens in the U.S. illustrates the explosive nature of intermediate and silicic eruptions often forcing nearby residents to evacuate the area (Christiansen and Peterson, 1981). So-called phreatomagmatic eruptions occur when lava gets in contact with water or ice leading to violent eruptions by abrupt water vaporization, thus producing large volumes of volcanic ash. The 2021 Fagradalsfjall eruption in Iceland, however, is a good example of molten lava pouring out from vents and fissures along **rift zones** or shield volcanoes.

Table 1 Chemical composition of volcanic rocks (Nockolds, 1954).

	<i>Alkali rhyolite</i>	<i>Dacite</i>	<i>Andesite</i>	<i>Tholeiitic olivine basalt</i>	<i>Nephelinite</i>
Silicon dioxide	74.57	63.58	54.2	47.9	39.07
Titanium dioxide	0.17	0.64	1.31	1.65	3.86
Aluminium oxide Al ₂ O ₃	12.58	16.67	17.17	11.84	12.82
Ferric oxide Fe ₂ O ₃	1.30	2.24	3.48	2.32	8.75
Ferrous oxide FeO	1.02	3.00	5.49	9.8	6.39
Manganese oxide MnO	0.05	0.11	0.15	0.15	0.26
Magnesium oxide MgO	0.11	2.12	4.36	14.07	6.14
Calcium oxide CaO	0.61	5.53	7.92	9.29	14.20
Sodium oxide Na ₂ O	4.13	3.98	3.67	1.60	4.09
Potassium oxide K ₂ O	4.73	1.40	1.11	0.54	2.07

Table 1 shows the range of silica content of volcanic rocks. As silica decreases the content of iron (Fe), magnesium (Mg), calcium (Ca), and sodium (Na) increases. These differences in chemical composition influence the rocks' susceptibility to weathering. In general, the basic rocks weather more rapidly owing to the ease with which Na-, Ca-, Mg-, and Fe-bearing silicate minerals undergo hydrolysis and dissolution. The rate of weathering is even faster in fine-grained pyroclastic material (Bonatotzky et al., 2021).

Rock weathering

The rate of weathering of volcanic rocks is influenced by their chemical and mineral composition, glass content, and particle size (Lowe, 1986; Hatano et al., 2021). Volcanic ash, for example, weathers comparably fast owing to its high glass content and large specific surface area associated with smaller particle sizes (Bonatotzky et al., 2021; Candra et al., 2021). Volcanic glass, however, varies in chemical composition. Felsic glass is high in silicon (Si), potassium (K), and sodium and is more resistant to weathering than mafic glass, which is high in iron and magnesium.

Artifacts such as arrowheads made of obsidian show little signs of weathering even after centuries of burial, primarily because they are felsic in composition and have low surface-area-to-mass ratios. It is a different matter with ash particles, called shards, which geologists and soil scientists often use as stratigraphic markers and evidence of ancient volcanic eruptions. Shards have high surface-area-to-mass ratios so that volcanic ash particles still identifiable as shards after deposition and buried for thousands of years are more likely to be felsic, as mafic shards would long have been weathered to clay minerals (Bleeker and Parfitt, 1974).

Soil formation

From a taxonomic standpoint, 'volcanic soil' is not a particularly useful term because a great variety of soils can have volcanic origins and or andic properties. Soils characterized by clay migration can form from volcanic rocks where rainfall is sufficiently high to leach bases, and conditions exist that favor activation and illuviation of clay. It is not unusual to find two soil orders, in close proximity that have formed from the same parent rock.

With the high porosity and large pores of most lavas and ash deposits, runoff is rare, and plants are able to establish quickly on these deposits (Kuzera et al., 2005). Nitrogen-fixing lichens and moss are the first to colonize lava flows, and, under warm and humid climates, dense forests can cover lava fields in less than a century. In humid areas, the soils that form first are organic soils of the Histosol Reference Soil Group. Histosols on volcanic parent material are often well drained and consist primarily of an organic surface horizon resting on rocks or fragmented materials (Hatano et al., 2021). If the underlying rock is A'a lava (Hawaiian lava flow of broken and rough surface) the soils are often Typic Folist or Folic Histosols, but if the rock is Pahoehoe lava (Hawaiian lava flow of smooth to ropy surface) the soil is commonly a Lithic Folist or Leptic Histosols. This distinction between them is crucial from an agricultural standpoint. Folic Histosols with their 'clinkery' A'a substrate are ideal for use as orchards, but their Leptic counterpart, with an unbroken and smooth rock substrate, is not. Fig. 1 shows some of the common parent materials of volcanic origin with or without pioneer plants or vegetation cover.

In the case of volcanic ash, plants may readily send roots deep into the loose ash deposit, and a rapid accumulation of organic matter occurs throughout the rooting depth. The first recognizable soil would most likely be a Vitric Andosol/Vitrand. As the names imply, those soils are Andosols/Andisols consisting mainly of unaltered or less altered glass fragments (Dethier et al., 1981).

Histosols and Vitric Andosols do not remain unchanged for very long. While soils change little in a human lifespan, one can, given the right circumstances, understand how volcanic soils change with time (Vilmundardóttir et al., 2015; Candra et al., 2021). Such circumstances exist in almost all volcanically active regions, e.g. Iceland, Japan, Indonesia, the Hawaiian Islands, New Zealand, which arise from the movement of tectonic plates over stationary hotspots, at subduction zones or mid-ocean ridges, rift zones (Arnalds, 2004; Bonatotzky et al., 2019; Saigusa et al., 1978; Stevens and Vucetich, 1984). The Hawaiian Islands for example formed

Fig. 2 A highly weathered [Andosol](#), an Acrudoxic Hydrudand. Photograph by G. Uehara.

from outpouring of lavas from the hotspot and are displaced in a northeasterly direction; they form a chain of islands that makes it almost perfect for studying volcanic soils. The age of the parent materials in the island chain ranges from recent on the island of Hawaii to 5 million years on the island of Kauai. Ten of the 12 soil orders of Soil Taxonomy occur in the island chain. Unlike Follic Histosols and Vitric Andosols that can form in less than a century, and are common on the youngest island of Hawaii, [Oxisols](#) and Ultisols that require prolonged weathering and leaching to develop, dominate on Kauai, the oldest island, while young Follics and Vitrandis do not occur there ([Beinroth et al., 1974](#)). The greatest diversity of soils exists on the island of Oahu, midway between Hawaii and Kauai. Here soils found on the older islands dominate, but young, post-erosional [volcanic eruptions](#) have rejuvenated part of the landscape. Soils that do not occur on the young islands, but peak on the intermediate islands, are [Vertisols](#). Their abundance on Kauai (the oldest island) is slightly diminished. The Vertisols form in valley floors on the dry, leeward side of the older islands. There, rainfall is lower and the bases that accumulate in the valley floor provide the right conditions for [smectite](#) clay formation. Vertisols do not occur on the young islands because valleys have not yet formed there. On the oldest islands in the wetter zones, Vertisols lose their bases and eventually become kaolinitic.

The soils developed from volcanic ash age much faster ([Bonatutzky et al., 2021](#)). Vitrandis quickly become ‘Haplic Andosols’ in the drier zone and hydromorphic Andosols in the wetter areas ([Bonatutzky et al., 2019](#)). The Hydrudands are some of the lightest soils in the world, with bulk densities of less than $0.5 \text{ cm}^{-3} \text{ g}$ and field water content by weight generally exceeding 100%. Owing to their porous nature, they are readily leached of bases and silica, leaving a residue high in hydrated [iron and aluminum oxides](#). These highly weathered, prematurely old soils occur on the youngest islands of Hawaii ([Fig. 2](#)).

Vertisols

A combination of basic parent material and a low-leaching environment often serves as a necessary condition for Vertisol formation. Sediment deposited by streams and rivers cutting through basaltic rock often provides the first condition, and the semiarid tropics that circle the globe north and south of the equatorial [humid tropics](#) provide the second.

[Table 2](#) gives the chemical [properties](#) of a Vertisol from Hawaii. They have low [organic carbon](#) contents and their main chemical and physical properties are determined by the large clay content ([Shoji et al., 1982](#)).

Oxisols or Ferralsols

A key feature of Ferralsols/Oxisols is the low [cation exchange capacity](#) (CEC) of their clay content. This condition is most likely to occur when the clay fraction is low in layered [silicate](#) clay and rich in iron oxides. [Volcanic rocks](#) low in silica and rich in ferromagnesium minerals weather rapidly to Oxisols under warm and humid conditions. While time and intense leaching can produce Oxisols from a variety of materials, volcanic materials with porous characteristics produce Oxisols with greater ease. The chemical composition and selected properties of an Oxisol formed from basic volcanic rock are given in [Table 3](#). The extreme weathering of the soil is indicated by its placement in the Acrudoxic subgroup (US Soil Taxonomy) and also by the increase in the

Table 2 Chemical composition and properties of a Gypsic *Vertisol* developed from basaltic *alluvium* (Lualualei series, island of O'ahu: fine, smectitic, isohyperthermic, Typic Gypsite; (USDA-SCS, 1978)).

LOI, loss on ignition; CEC, [cation exchange capacity](#).

1 mol l⁻¹ KCl pH in the ferralic or oxic horizons midway in the profile. In the ferralic or oxic horizons the pH measured in 1 mol l⁻¹ KCl is higher than that measured in water, indicating that the net charge of the soil material is positive. Soils with these characteristics are infertile, but can be made productive with phosphorus fertilization, as well as liming with [calcium silicate](#) rather than [calcium carbonate](#) (De Souza et al., 2008; Montalvo et al., 2015).

Ultisols or Acrisols

Ultisols or Acrisols and Oxisols or Ferralsols have developed synchronously on the same geomorphic surface on Kauai in the Hawaiian Islands. The Ultisols, however, always occur, where [soil creep](#) activates and mobilizes clay along sheer planes in the [subsoil](#) (Beinroth et al., 1974). The chemical composition and properties of such an Ultisol are given in [Table 4](#). The same shearing action leads to the formation of Alfisols in drier locations, where leaching is less intense and basic cations are retained in the profile.

Andisols or andosols of volcanic origin

If one had to choose a soil to represent the class of soils we call volcanic, it would be an Andisol/Andosol, a soil with andic properties. Those soils have two characteristics, which make them unique. They contain large amounts of short-range-order and non-crystalline materials, and have low bulk densities. Two short-range-order minerals commonly found in highly leached and weathered soils from pyroclastic parent materials are [allophane](#) and [imogolite](#) (Bleeker and Parfitt, 1974; Parfitt, 1975; Shoji et al., 1982). These minerals have extremely high specific surfaces (approximately equal to 1000 m² g⁻¹) and pH-dependent charge. The high specific surface of the inorganic colloids enables the soil to sequester large quantities of organic matter. The prefix 'Ando' is the Japanese word for 'dark,' used to describe the low chroma of organic-rich [volcanic ash soils](#) of Japan. In Japan, where the ash is generally high in silica and low in iron, organic matter imparts a nearly black color to the soil (Shoji et al., 1982; Hatano et al., 2021).

The chemical composition and selected chemical properties of two Andosols, one developed in a perudic (precipitation >> evapotranspiration; water saturated soil conditions long enough to cause oxygen deficiency), and the other in a [ustic](#) (seasonally dry, but moist during the vegetation period) moisture regime, are given in [Tables 5 and 6](#). Both soils are excellent agricultural soils; the wetter soil requires careful nutrient management and the drier one requires irrigation for profitable farming. However, the low bulk densities of Andosols may lead to severe soil erosion under intensive land-use ([Fig. 3](#)).

Andosols of non-volcanic origin

Since the late 1950s an increasing number of soils are described as having both andic and spodic or podzolic properties developed in non-volcanic parent materials ([Schönhals, 1957](#)). An overview is given in [Bäumler et al. \(2005\)](#). Based on their physico-chemical properties they were named 'Lockerbraunerden' (very friable Cambisols), Cryptopodzols, or non-volcanic or non-allophanic Andosols because they could not be classified properly ([Bargon, 1960; Blaser et al., 1997; Kleber et al., 2003; Dümig et al., 2008; Iamarino and Terribile, 2008; Mileti et al., 2017; Terribile et al., 2018](#)).

Common facts at all sites described so far, are.

- (i) acid parent materials,
- (ii) leaching environment,
- (iii) comparably large amounts of oxidic Fe- and Al-compounds in the soil matrix, and high Fe- and Al-contents in the parent materials,
- (iv) large contents of soil organic matter throughout the soil matrix,
- (v) a lack of short-range-order clay minerals (non-allophanic),
- (vi) extremely low bulk densities, partly <0.5 g cm⁻³ despite clay contents of >50%,
- (vii) high porosity and strong P-retention.

In general, non-volcanic andic soils are also characterized by both andic and spodic/podzolic properties, but without visible eluvial and illuvial horizons ([Blaser et al., 1997; Bäumler et al., 2005](#)). They lack coarse fragments indicating possible eolian deposits or a considerable degree of soil development, or both. Typical features are thixotropy of A and B horizons, as well as extremely stable (micro-)aggregates resembling a pseudosand-like structure. These aggregates were highly resistant to conventional dispersion treatments before particle-size analysis ([Bäumler et al., 2005](#)). The soil properties were specified as silandic, aluandic, transitional alu-sil-andic, and recently as ferro-andic ([Bäumler et al., 2005](#)). Most sites are located in undisturbed mountain environments with native forests or non-intensive land-use. Non-volcanic eolian additions mixed up with the in-situ weathered soil material could be identified for some of the soils described ([Mileti et al., 2017](#)). Radiocarbon dating of the soil organic matter at 1.5-m depth of the soil shown in [Fig. 4](#) gave ages of more than 15,000 years despite recent rooting, leaching of dissolved organic matter, and biodecay ([Bäumler et al., 2005](#)). Age calculations based on soil development indices provided ages of 60–70 ka at the Bhutan sites ([Fig. 4](#)), and up to more than 200 ka for a site in the Khumbu Himal, eastern Nepal ([Dorji, 2016](#)).

2.5-0 cm. O. Partially fragmented +decomposed litter.

0-17 cm. A. Very dark greyish brown (2.5Y3/2) clay, fine and medium granular to subangular blocky, 52 % clay, 0.49 g cm⁻³, 11.7 % Corg.

17-24 cm. AB. Olive brown (2.5Y4/4) silty clay, medium granular to subangular blocky, 50 % clay, 0.59 g cm⁻³, 5.8 % Corg.

24-49 cm. B1. Brownish yellow (10YR6/8) silty clay loam, weak discontinuous clay skins, 38 % clay, 0.44 g cm⁻³, 2.3 % Corg.

49-101 cm. B2. Yellowish brown (10YR5/8) clay loam, weak discontinuous clay skins, 28 % clay, 0.69 g cm⁻³, 2.2 % Corg.

101-148 cm. B3. Yellowish brown (10YR5/8) silty clay loam, coarse subangular blocky, no stones up to here, 37 % clay, 0.84 g cm⁻³, 1.2 % Corg.

148-200 cm. CB. Brownish yellow (10YR6/8) sandy clay loam, massive to granular, abundant stones, 22 % clay, 1.24 g cm⁻³, 0.5 % Corg.

200+cm. C. Mica schist, slightly weathered, massive.

Fig. 4 Non-volcanic andic soil from Central Bhutan: 90°44'E, 27°32.2'N; 3025 m asl; 7.6 °C annual temperature, 1100 mm annual precipitation; mica schist parent material. Photograph: R. Bäumler.

The well-established international classification systems address andic soils as commonly dark colored soils of volcanic areas typically developed from pyroclastic materials, and characterized by a moderate extent of soil development containing short-range-order minerals and or organo-metallic complexes. Andic properties from non-volcanic materials are mentioned as occurring marginally (USDA-SCS, 1999; IUSS Working Group WRB, 2015). Researchers working on non-volcanic andic types of soil commonly agree that their distribution is widely underestimated, however (for example Fig. 5 shows the probability of their occurrence on the southern slopes of the Himalayas). At present their classification across the globe is unsatisfactory. A re-definition of their classification is proposed towards andosolization as the dominant soil forming process (in non-volcanic mountain areas or undisturbed ecosystems) independently of the origin of the parent materials, or even a new soil type has been suggested that clearly separates these from Andosols or Andisols *sensu strictu* (Kleber et al., 2003; Bäumler et al., 2005; Iamarino and Terribile, 2008).

There are few options to classify non-volcanic andic soils at present, as spodic horizons may have andic properties, but Andosols should not have a spodic horizon (IUSS Working Group WRB, 2015). Non-volcanic andic soils with spodic horizons are therefore classified as Podzols/Spodosols, because of the presence of a spodic horizon (unless buried deeper than 50 cm) is given preference over the occurrence of andic properties. Non-volcanic andic soils missing a single spodic criterion have to be classified as Andosols/Andisols.

Questions remain at present about the role of non-volcanic eolian additions (Mileti et al., 2017), and or multiple freeze-thaw cycles inducing at least part of the specific properties. Moreover, it is debated that andosolization could be considered a common soil forming process independent of the parent material, but considerably endangered by erosion, and therefore not well preserved

Fig. 5 Occurrence of alu-andic Andosols on the (non-volcanic) southern slopes of the Himalayas (Nepal, Sikkim/India, Bhutan, Tibet/China) between 2000 and 3500 m asl. On the map, the darker the orange color, the higher is the probability of occurrence (SoilGrids 2.0: Poggio et al., 2021).

(McDaniel et al., 2018). And in addition, almost all research papers indicate an under-estimated role of polyvalent Fe ions and/or oxidic iron compounds for ferro-andic properties (Bäumler et al., 2005).

Human interactions with volcanic soils

Volcanic soils may have special meaning to people living in humid regions where the soil would be less fertile than under normal circumstances, but are maintained by periodic additions of nutrient-rich ash from a neighboring volcano (Lubis et al., 2021). The advantage of having an adequate supply of water and nutrients in contrast to having one or the other was, for our ancestors, the difference between being able to form creative, sedentary communities in contrast to simply surviving by hunting and gathering. Thus, it may not be the soil itself but the presence of an active volcano nearby that makes volcanic soils what they are.

Our human ancestors may have avoided extinction and evolved by adapting to the diverse and ever-changing volcanic environments. The soils rich in mineral nutrients, constantly rejuvenated by sprinklings of volcanic ash support large herds of herbivores and their predators, and some of the highest nonurban human population densities (Small and Naumann, 2001).

When modern humans left their native habitats for any reason, then crossed Asia and the Bering Straits, they encountered the North, Central, and South American segment of the 'Ring of Fire' that circles the Pacific. Like the rich [alluvial soils](#) of the Nile, Tigris, Euphrates, and Indus rivers that enabled humans to shift their energies from hunting and gathering to creative endeavors, the fertile and well-watered [volcanic soils](#) all around the Ring of Fire provided new settlers with the means to do the same (Willerslev and Meltzer, 2021).

Even today, the influence of volcanic soils on human society is evident. In Indonesia, for example, nearly half of its population live on the volcanic islands of Indonesia. Efforts to move whole communities from densely populated areas to the larger and less densely populated neighboring islands have been difficult. Villagers accustomed to farming [Andosols](#) with characteristics similar to the one shown in [Table 5](#) found it difficult to survive on the less fertile [Ultisols](#) of other islands with features similar to those shown in [Table 4](#).

Today [science and agro-technology](#) enable farmers to understand and overcome soil constraints, but only a century ago [soil fertility](#) determined to a large degree the outcomes of human interactions with the environment. This is still true in many developing countries, where science-based soil management practices have yet to be adapted. Volcanic soils of Africa, Asia, and Latin America that helped people in the past now need new ideas and technologies to perform and contribute to human well-being in a fast changing environment.

Conclusions

Soils developed from volcanic parent materials are found all over the world in present or past tectonically and/or volcanically active areas. The story of their pedodiversity is recorded by the chemical composition, the mineral structure and/or the surface area of the volcanic parent materials. The specific soil properties are further explained by the period of soil development, respective age of the soils, and the specific site conditions. The site conditions are in turn controlled by the climate, the relief, the volcanic or tectonic activity, and human impact. Volcanic soils are in general very fertile. Land-use intensity is high provided that the moisture conditions are not too wet or too dry, and as long as the relief is not too high. Volcanic soils are often severely endangered on steep slopes by thixotropic features inducing landslides, especially in Andosols developed from volcanic ash. A focus of future research should be on soil conservation measures against erosion at sites of intensive agriculture. Moreover, the processes of soil formation and the development of andic properties from non-volcanic parent materials are yet not fully understood.

Abstract

Pedometrics is concerned with the application of mathematical and statistical methods to the study of the distribution and genesis of soils. Here, we describe the main areas that pedometric research addresses: distribution of the soil pattern in character space, spatial and spatio-temporal soil variation, quantitative evaluation of the utility and quality of soil, and quantitative pedogenesis. To these main areas akin to the problems of pedology, pedometrics considers and represents uncertainty. Pedometric research is undeniably in an expansion phase and has now many areas of application at the interface with many questions relevant to the sustainable growth of our societies.

Key points

- Succinctly describes the four main areas of pedometrics.
- Pedometric research can contribute to many areas of soil science.

Introduction

The term 'pedometrics', first coined by McBratney in the late 1980s, 'is a neologism derived from the Greek roots pedos or πεδος (soil) and metron or μετρον (measurement)'. It is used in a similar fashion to other words such as biometrics, psychometrics,

Table 1 Types of quantitative models used for soil studies with examples and sources of uncertainty.

Causality and/or uncertainty	Model		
	Deterministic	Stochastic	Nonstatistical
Empirical	Generalized linear models, numerical taxonomy, Jenny functional relations and canonical ordination	Time series, spatial processes, temporal and spatial variation of soil properties, Markov chain models	Fuzzy systems, Machine learning
Mechanistic	Flow and diffusion of soil plastic materials, profile and landscape development	Indeterminate	Indeterminate
Uncertainty	Imprecise measurements, model uncertainty	Random process, probability	Vagueness, ambiguity, and fuzzy geostatistics

Fig. 1 A timeline of the growth of pedology and pedometrics. Modified from McBratney AB, Odeh IOA, Bishop TF, Dunbar MS, and Shatar TM (2000) An overview of pedometric techniques for use in soil survey. *Geoderma* **97**: 293–327.

econometrics, chemometrics, and, the oldest of all, geometry. Furthermore the term covers two main ideas—the ‘soil’ or ‘pedo’ part, which corresponds to that branch of soil science we call pedology, and the ‘metrics’ part, which is restricted to mathematical and statistical methods. Simply defined, pedometrics is the use of quantitative methods for the study of soil distribution and genesis, and as a sustainable resource. Another problem-oriented definition is ‘soil science under uncertainty.’ In this sense pedometrics deals with uncertainty in soil models that describe deterministic or stochastic variation, vagueness, and lack of knowledge of soil properties and processes (Table 1). Thus, mathematical, statistical and numerical methods could be applied to resolve the uncertainty and complexity inherent in a soil system model, including numerical approaches to classification, which deals with supposedly deterministic variation (Webster, 1994).

Pedometrics is not new, as mathematical and statistical methods have been applied to soil studies since the 1900s (statistical research by R. Fisher at Rothamsted) and more intensively since the 1960s and 1970s. However, it is now a technical branch of soil science complementing traditional pedology. Over time the use of computers has increased in both fields, and the difference between the two has decreased and, in some cases, overlapped. Due to new demands for quantitative soil information required for global-scale models, regional environmental planning, and field-scale agricultural land management, traditional pedology has become more quantitative through the increased use of digital soil data in computerized soil information systems. Concurrently, pedometrics has emerged as a collection of quantitative tools, which are increasingly being used to account for conceptual pedological models of soil variation. As of 2021, there is a strong and growing overlap and synthesis between ‘traditional’ pedology and quantitative pedology or pedometrics (as shown in Fig. 1).

Methods and problems

Pedometrics: Principles and hypotheses

As the definition implies, pedometrics encompasses the whole quantitative approach to the study and description of soil. It also involves the use of mechanistic, stochastic, deterministic, and empirical models (Table 1). A more restricted form of pedometrics is one that involves applications of statistical and probabilistic modelling to soil variation. Pedometric principles are therefore embodied in (geo-) statistical modelling of pedological processes and the associated phenomena as they influence soil variation, and the associated model uncertainty.

Pedometrics is therefore aimed at resolving or testing a number of questions or hypotheses (McBratney and Lark, 2018):

1. What is the pattern of soil distribution in character space, i.e. soil taxonomy?
2. How does the soil vary spatially and temporally?
3. What are the utility and quality of soil?
4. What are the causal factors of soil formation, i.e., soil genesis?
5. What is the uncertainty of modelling the spatial pattern of soils, i.e., is a model an accurate representation of reality?

With the exception of (5), these hypotheses dovetail well with the requirements of conventional pedology. Although developments in pedometrics in the past were restricted to statistics and probability, increasingly the utility of soil is the subject of pedometric research and mechanistic models are being applied and developed to model soil processes.

Soil measurements and properties

To model soil quantitatively, we need to perceive it, i.e., sense it or measure some quality or quantity of it. In other words, how do we represent soil properties numerically to model their variation mathematically and/or statistically? Ever since the advent of modern environmental science, technological advances have improved immensely the way we characterize or measure the quality and/or quantity attributes of soil. Soil measurement techniques include direct measurements, visual observations, and remote sensing (including proximal, airborne, and space-based modes of sensing).

Field properties: Hard and fuzzy descriptors?

Other than color, many soil morphological properties, required in routine soil surveys, are described in somewhat vague terms. For example, soil structure grade is described as 'structureless' or 'weak' or 'moderate' or 'strong' in many national soil survey handbooks. To make the grades more amenable to quantitative analysis (e.g., multivariate statistical analysis) these terms are usually coded as 0, 1, 2, and 3, respectively. But because of the vagueness in the linguistic characterization, fuzzy coding, which accounts for uncertainty or lack of clear boundary between the grades, has been used. Other morphological descriptors such as soil aggregate (structure) size classes, e.g., 'fine,' 'medium,' and 'coarse,' may be given linguistic variables which could be fuzzified to determine the degree of truth that a given soil layer is characterized by. Simple examples of fuzzy coding are presented in Table 2.

Soil spectroscopy

Measurement of soil properties has gained tremendously from advances in technology, particularly in spectroscopy. Soil spectroscopy is loosely defined as the study of the spectral signature of a soil material. The spectral signature of a soil is primarily a function of its mineral and organic composition since the soil is formed from the transformation of rocks, organic matter from plants and organism activity. Thus, a soil type has a unique spectral reflectance curve. Spectroscopic measurements can be proximal or remote, when mounted on a satellite, plane or drone. Proximal measurements might be done in situ on the soil profile using portable field spectrometers or in the laboratory. Because of the large number of soil characteristics that a soil spectrum contains, it is said that spectroscopic measurements are cost-effective and fast, compared to conventional methods of soil analysis (Nocita et al., 2015).

The visible (400–700 nm) and infrared (400–25,000 nm) range of the electromagnetic spectrum is of particular interest to soil scientists. Infrared spectra have encoded information on both organic and inorganic soil material. The mid-infrared range (2500–25,000 nm; 400–4000 cm⁻¹), contains distinct absorption features for soil organic matter and mineralogy. These absorption features have overtones and combinations in the visible and near-infrared (vis-NIR) range (400–2500 nm), which means that soil organic and mineral characteristic are also reflected in the vis-NIR range but with fewer, broader, and more complex (i.e. non-specific) absorption bands. Fig. 2 shows three vis-NIR spectra for soil samples with different compositions.

Table 2 Fuzzy coding of structural type.

Type	Horizontality	Verticality	Flatness	Accommodation
Platy	1.0	0.1	1.0	1.0

Fig. 2 Vis-NIR spectra of three soil samples from wheatbelt of southern New South Wales, Australia: a soil with 12% total organic carbon and two soil samples with low total organic carbon content (<1%) of which one has 74% clay and 19% sand and the other 5% clay and 91% sand.

Pedometricians have extensively investigated the predictive power of such spectra to replace and complement soil analyses. Mathematical transfer functions are used to correlate the spectral wavelengths (the independent variable) to laboratory-measured values of soil properties (the dependent variables). Relatively simple models can be used, for example linear regression on user-defined wavelengths, but more complex models exist, such as principal component analysis and partial least-squares regression. Both models consider the whole spectra for estimating their parameters and make use of reduction dimensionality (principal component analysis). More recently, pedometricians have also considered machine learning models, with some success. Once calibrated, the model is used to predict the soil properties using spectral information only. These soil property estimates are stored together with the soil spectral information into spectral libraries. Lately, efforts have been made to combine and standardize soil spectra from various instruments into large, regional and global soil spectral libraries. Research is also on-going to fuse multiple sensors and instruments to obtain more precise estimates of soil properties.

Pedotransfer functions

The term ‘pedotransfer function’ (PTF) is generally defined as translating the raw soil data into more useful information. It can also be defined as predictive functions of certain soil properties difficult to obtain from other easily, routinely, or cheaply measured properties (Van Looy et al., 2017). The most readily available data come from soil survey, such as field morphology, texture, structure, and pH. The PTFs add value to the basic soil data by translating them into predictors of other more laborious and expensively determined soil properties. These functions fill the gap between the available soil data and other properties that are more useful or required for a particular model or quality assessment. A simple illustration of how to apply PTFs to practical problems is shown in Fig. 3.

Soil spectral inference systems also rely on PTFs to populate soil databases. Spectral inference systems combine soil spectral data to infer a set of basic soil properties, and PTFs to estimate another set of soil properties more difficult to measure or without spectral response, such as permanent soil wilting point or field capacity. The PTFs are found in the literature and combined into a network structure to create an inference system. One of the main features of soil spectral inference systems is the quantification and propagation of uncertainty, using methods such as model ensemble by bootstrap and aggregation (See chapter on this topic in Encyclopedia).

Quantitative soil geography

Soil classification and soil map units

The pattern of soil in the landscape is as a result of effects of soil-forming factors, namely: climate, organisms, parent material, topography, and time (usually referred to as ‘clorpt,’ but recently extended to ‘scorpan’—see Eq. (2), below). These factors, particularly climate and parent material, produce broad patterns of soil in geographic space. The complex combination of these factors is what causes repetitive patterns of soil in the landscape, which form the basis for soil classification, identification, and mapping. In traditional soil classification, both the conceptual and real classes are qualitative and have no clear-cut boundary. Pedologists have, in the past, attempted to avoid these by applying numerical classification to complex soil data. Soil classification, in both geographical and taxonomic space, is a simple representation of complex, and sometimes repetitive patterns of soil in the landscape. Class identification, on the other hand, is aimed at matching classes that are conceptually described (usually in a classification system) with reality—represented by data obtained by soil morphological description and measurements.

A soil map unit is a collection of areas that are relatively homogeneous in soil constitution or miscellaneous areas that constitute different soil components or both. In a given survey region, a map unit differs in some respect from all others and can be uniquely identified on a soil map. A soil map delineation, on the other hand, is an individual area on the map, bounded by other delineations or the map boundary. Usually a delineation contains the dominant components in the map unit name, but it may

Fig. 3 A simple example of pedotransfer functions (PTFs) for the Centre-Val de Loire region (France): (A) particle-size fractions were interpolated on to a fine grid from a set of point measurements; (B) horizon (5–15 cm) soil water at field capacity (SMFC) and soil moisture content at permanent wilting point (SMPWP) were in turn estimated through a PTF expressed as a function of particles sizes; (C) available water capacity is estimated by multiplying the SMFC subtracted from the SMPWP by the soil layer thickness (in mm), assuming all soil is fine earth. Modified from Román Dobarco, MR, Bourennane, H, Arrouays, D, Saby, NP, Cousin, I, and Martin, MP (2019) Uncertainty assessment of GlobalSoilMap soil available water capacity products: A French case study. *Geoderma* **344**: 14–30.

not always contain a representative portion of each kind of inclusion. Soil boundaries can seldom be shown with complete accuracy on soil maps; hence parts of adjacent polypedons are inadvertently included or excluded from delineations. This problem has been the stimulus for paradigm shifts in soil classification in the latter part of the 1990s; hence the applications of numerical hard and fuzzy classification systems in soil science.

From the 2010s onwards, there was a renewed interest in numerical soil classification, after nearly two decades of meagre activity and progress. Two classification systems, the World Reference Base (WRB) and Soil Taxonomy, are considered global soil classification systems. Both systems, however, also have several shortcomings for local applications. A better communication between regional soil classification systems was attempted, for example by standardization using taxonomic distance. All soil classifications can be evaluated in the multi-dimensional space of the soil data with dimensionality reduction, and by computing centroids for each class of any system. Numerical methods applied to soil classifications have other advantages. For example, they enable the quantification of similarity between soil profile descriptions or between genetic horizons (Hughes et al., 2018).

Fuzzy classes and the breakdown of the classification paradigm

Traditionally most classification systems are composed of mutually exclusive classes in order to conform to discontinuous soil variation embedded in the traditional concept of soil map units. But soil variation is more continuous than discrete. The pioneer work in pedometrics, involving computer-based numerical classification, was designed to address this limitation, among others (McBratney et al., 2000). While the applications of numerical soil classification to soil studies are, to some extent, based on continuous representation of soil in space, their results are still interpreted in terms of 'hard' classes. There is also lack of any spatial coherence for the classes to be mapped, despite some attempts with, for example, spatially weighted classification. Recent advances are based on fuzzy sets to optimize the quality of prediction of the resulting classification, and which take cognizance of the continuous nature of soil variation and nonlinearity in the inter-attribute relationships.

The first application of fuzzy set theory in soil survey was principally for classification. Two different but complementary approaches to grouping individuals into fuzzy classes in soil science are: (1) fuzzy *c*-means (FCM, also known as 'fuzzy *k*-means'), and (2) the semantic import model (SI).

The FCM algorithm for improved predictive classification by providing for membership to an extragrade class is based on the objective function, defining the within-class sum-of-square errors, J_E , expressed as (McBratney and Odeh, 1997):

$$J_E(M, c) = \alpha \sum_{i=1}^n \sum_{j=1}^c m_{ij}^{\varphi} d_{ij}^2 + (1 - \alpha) \sum_{i=1}^n m_{i*} \sum_{j=1}^c d_{ij}^{-2}, \quad (1)$$

where c is the number of classes, n is the number of individuals or pedons; m_{ij} is the membership of an individual i in class j ; φ is the fuzziness exponent ($1 < \varphi < \infty$); d_{ij} is the character space between the feature value of an individual, i , and the feature centroidal value for class j ; α is the parameter that determines the mean value of m_{i*} , which is the membership value of an individual, i , in the extragrade class.

The SI model was developed primarily for land evaluation. The need to use fuzzy set theory in land evaluation, such as that defined in the Food and Agriculture Organization of the UN (FAO) framework, arises because basic soil information used for land evaluation is mostly described by seemingly vague terms such as 'poorly drained,' 'slightly susceptible to soil erosion,' and 'moderate nutrient availability.' Not even when these terms are defined precisely is the qualitative ambiguity removed. Usually, the land evaluator's aim is to produce a set of clearly defined classes of land qualities based on specified land use requirements. These subsequently provide the means of transferring information about the soil and its use. As land qualities are complex attributes that are derived from land characteristics such as topography, soil, water, or biological and human activity, subsequent Boolean logical operations in the process of land evaluation tend to throw away much useful information.

Pedodiversity

Measuring pedodiversity within an area is a way of measuring soil variation, usually using pre-classified soil entities such as taxa or properties. The diversity of pedological entities such as pedotaxa, pedogenetic horizon and soil properties, as well as their spatial and temporal patterns influences several ecosystem functions that the soil provides. A more diverse soil is also more resilient against disturbance and stress caused by unsound soil management practices.

The concept of diversity contains two fundamental components which apply to pedodiversity (Ibáñez and Bockheim, 2013): (i) the richness, i.e., the number of soil types (soil classes) in the area of interest or within a level of the taxonomic system and (ii) the evenness, i.e., the relative number of soil types or classes. Soil scientists have contributed to developing indices of pedodiversity, most of them being similar to the well-known indices of ecological and biological diversity developed by ecologists and biologists. Such indices encompass species richness and abundance models, few of them incorporate the two into a single index, the most popular of which is the Shannon diversity index, defined by:

$$\text{Shannon diversity index} = - \sum_{i=1}^n p_i \times \ln p_i, \quad (2)$$

where p_i is the proportion of the i th soil type relative to the total number of soil types n in the area of interest or level of the taxonomic system. When the area is composed of a single soil type, it equals zero and is unbounded otherwise as the number of soil types increases. When applied to existing soil classification systems, several authors have found clear relationships between the number of soil types (i.e., the pedodiversity) and the size of the area surveyed. Such indices were applied at the global scale, where it was found that some continents are more diverse than others.

Pedometricians contended that taxonomic distance between soil types should be included in the computation of pedodiversity indices because the similarity differs among taxa. These can be included by indices of quadratic and taxonomic entropy.

Space and time prediction

The clorpt approach

As previously stated, the 'clorpt' methods are based on the empirical-deterministic models that originated from Hans Jenny's *Factors of Soil Formation*. Jenny's state-factor equation, in its extended form, is expressed as (McBratney et al., 2003):

$$S = f(s, c, o, r, p, a, n), \quad (3)$$

where S is some soil properties or soil type as a function f of state factors: s as some other soil property at a point, c as climate, o as organisms, r as relief, p as parent material, a as time or age, and n as space or spatial position. Soil spatial variability is therefore considered as being causative realizations of the complex combinations of soil-forming processes as influenced by the soil-forming factors. The scorpan function (Eq. (3))—in its original form, the clorpt—earlier in the twentieth century stimulated numerous studies, mainly quantitative prediction of soil attributes, which we shall treat in a later section. Until recently, because data on soil classes were non-quantitative, the scorpan methods were only restricted to predicting soil attributes measured on a continuous scale.

Models such as that expressed in Eq. (3) can be derived for predicting soil classes or soil types using various techniques, for example logistic regression, classification trees and other machine learning models. Logistic regression is designed specifically for situations in which we have a dichotomous (nominal or ordinal) dependent variable (e.g., soil classes), in comparison to classical linear regression typically used for continuous dependent variables (e.g., soil pH value). Several problems arise when a dependent variable is binary: the error terms are non-normal and their variance is non-constant. Although the errors are not normal, this method still provides unbiased regression estimators that are approximately normal if the sample size is large. Classification tree algorithms and other machine learning models, on the other hand, search for combinations of values of independent variables (e.g., Jenny's state factors or attributes derived from them) that best predict the value of the dependent variable (e.g., unordered factors such as soil classes). Prediction quality is based on criteria such as the within-group noises, variance, or statistical significance of the conditional frequency distribution of values for the dependent variable, conditioned on the answers to questions asked. A digital map of soil suborder classes produced by the classification tree model is shown in Fig. 4.

The scorpan approach

The 'scorpan' approach (Eq. 3) earlier in the twentieth century stimulated numerous studies in quantitatively predicting soil attributes measured on a continuous scale. Many of the earlier studies, and indeed some recent examples, were based on general and bivariate-simple linear regression, although multiple polynomial regression models were occasionally applied. But due to

Fig. 4 Predicted soil classes for the Edgeroi area in accordance with Australian Soil Classification. Reproduced with permission from McBratney AB, Odeh IOA, Bishop TF, Dunbar MS, and Shatar TM (2000) An overview of pedometric techniques for use in soil survey. *Geoderma* 97: 293–327.

nonlinearity in the correlations among many soil variables, and indeed of many of the soil variables with ancillary variables, robust methods such as generalized linear models (GLMs), generalized additive models (GAMs), and random forest (RF) have been developed and applied. Another development is the artificial neural network models, which are nonparametric modelling techniques that mimic the neural networks of the brain. The networks are composed of processing units, or neurons, which are organized into layers, i.e., input, hidden, and output layers. We shall describe mapping based on machine learning in the next subsection.

The problem is that while the classic models or the more robust methods may take care of the deterministic relations, they do not account for spatial autocorrelations of soil properties, especially at the local level. To solve this problem, the pioneer pedometricians initiated the application of geostatistics (which was primarily developed for the mining industry).

Geostatistics

Matheronian geostatistics is based on the theory of regionalized variables, which allows us to consider spatial variability of a soil property or even soil types, if quantified, as a realization of a random function represented by a stochastic model. The generic geostatistical method of spatial interpolation is termed 'kriging' in its various forms: simple, ordinary, lognormal, and disjunctive kriging (Webster and Oliver, 2007).

In geostatistics, the variogram is a primary requirement for spatial prediction or kriging of a target geographical feature. The variogram can be obtained by computing the spatial correlation or covariance between pairs of samples at certain distances apart in a data set to produce empirical semivariances. The plot of the semivariance and the corresponding distance or lag at which the pairs are separated produce the variogram. The latter describes the magnitude, spatial scale, and the general form of variation of a given variable (Heuvelink and Webster, 2001). An example of an experimental variogram is shown in Fig. 5, together with several exponential models based on different fitting methods.

The first major applications of kriging, in its ordinary and univariate form, for soil studies were in the early 1980s. Since then ordinary kriging has been widely used in various subfields of soil science, including soil reclamation, soil classification, and soil pollution. Major limitations of the univariate geostatistics technique of kriging are due to the assumptions of stationarity, which are not often met by the field-sampled data sets and, of course, the often-cited requirement of large amounts of data to define the spatial autocorrelation. However, with increasing availability of ancillary information, the lack of adequate samples has been partially solved. The univariate use of kriging is also limiting in situations of complex terrain where the soil-forming processes are themselves complex. In such situations there is the need to model both the structured and the spatially dependent components of the soil variable. Also there are economic and logistic reasons for including the ancillary variables influencing soil variability, especially if the latter are more readily and cheaply available. As both the soil and exogenous factors are multivariate, the most obvious choices are appropriate combinations of multivariate or univariate analysis using the scorpan factors and geostatistical methods. These combinations constitute the hybrid techniques.

The hybrid of scorpan and geostatistics

The hybrid techniques for soil survey and mapping are based on various combinations of the geostatistical and multivariate or univariate scorpan methods. Let us suppose that a data vector describing a soil property is a random variable Z , determined at locations s in a region $\mathfrak{A}$, $s_i (i = 1, \dots, N; s_i \in \mathfrak{A})$, and consisting of three components as:

$$Z(s) = m(s) + Z_1(s) + \varepsilon(s), \quad (4)$$

where m is the local mean for the region, Z_1 is the spatially dependent component, and ε the residual error term, spatially independent. Now there may be situations where m varies and is dependent on some exogenous factors such as the scorpan factors

Fig. 5 An experimental variogram fitted with exponential models based on different fitting techniques.

at spatial location s . In other words it is deterministically related to some causative factors (in geostatistics parlance, the variable is said to exhibit a trend). Wherever trend exists, ordinary univariate kriging is inappropriate. Several methods have been designed to accommodate the trend.

Universal kriging has been the commonly used method to accommodate the trend or 'changing drift,' as it is sometimes known, in a soil variable. Universal kriging is a combination of the standard model of multiple-linear regression and the geostatistical method of ordinary kriging, which is also analogous to combining scorpan methods with univariate kriging, but only using the geographic coordinates for determining the drift (the n factor of the scorpan model). Another approach is to use an intrinsic random function of order k (IRF- k), which has been used to accommodate the varying nature of the trend in a regionalized soil variable. The term ' k ' represents the order of polynomial trends: $k = 0$ means constant drift, and the IRF- k is equivalent to the ordinary kriging system of equations. If $k = 1$, we have linear drift; $k = 2$ yields quadratic drift; but where there is no trend but deterministic relationships are with some known or readily available and inexpensive covariates (scorpan factors) or other easy-to-measure soil variables, co-kriging has played a major role in efficiently predicting the target soil variable. Universal co-kriging is also possible when considering the trend and covariation with one or more secondary variable.

Co-kriging is the multivariate extension of kriging that allows the inclusion of more readily available and inexpensive attributes in the prediction process. There are many instances in soil survey where the scorpan factors such as topography, time, and variable parent material, are easily discernible or are either readily available and/or are cheap to obtain. The most efficient way to predict the expensive-to-measure target soil variable, the variation of which is affected by the scorpan factors, is to supplement the information of the sparsely sampled target variable with more densely available information from a cheap to obtain variable.

Regression-kriging (RK) is another hybrid method that combines either a simple/multiple-linear regression model or machine learning (for example a variant of GLM, GAM, RT or RF) with ordinary, or simple, kriging of the regression residuals. The assumption here is that the deterministic component (m in Eq. 4) of the target (soil) variable is accounted for by the regression model, while the model residuals represent the spatially varying but dependent component (Z_1 in Eq. 4). If the exogenous variables used in the regression equation are available at more dense locations than the target variable, the equation can then be used to predict m on to those locations. The Z_1 can also be predicted to the same locations by the simple kriging system of equations, and then added to the m to obtain Z^* . A variant of RK is kriging with uncertainty, which introduces regression residuals (as representing model uncertainty) into the kriging system used to predict the target soil variable. This reduces the extrema of the target soil variable and therefore produces a smoother function of the predicted values. Another variant of RK, kriging with external drift (KED), is a hybrid technique that integrates the universality conditions into the kriging system using one or more of the ancillary drift variables. It is similar to universal kriging, but using an ancillary variable to represent the trend (Fig. 6). As shown in Fig. 6A, a regional digital map of cation exchange capacity (CEC) has been produced using KED with elevation as the external drift. Comparing this map with the one produced using RK (Fig. 6B) indicates a slightly more smoothed map produced by KED than RK.

Machine learning

Machine learning (ML) has emerged since the 1990s as a set of algorithms useful for soil mapping, but it is in the past decade only that the use of ML algorithms in soil science have burgeoned. Machine learning refers to a large set of non-parametric and data-driven algorithms developed for data mining and pattern recognition purposes, and now frequently used in all fields of soil science for classification and regression purposes (Wadoux et al., 2020). The increase in spatial prediction with ML corresponds with the recent availability of large digital soil databases and computer resources. In the previous Section we discussed some limitations of geostatistical mapping of soil, such as stationarity, normal distribution of the residuals, and difficulties for non-linear modelling of soil properties using numerous and cross-correlated covariates, among others. Machine learning can handle most of the limitations of geostatistical models when the amount of data to calibrate the model is sufficiently large. Indeed, ML algorithms do not make assumptions on the distribution of the soil properties and can accommodate numerous, categorical and continuous, and correlated covariates as predictors.

Examples of ML algorithms are, for example, regression tree, random forest (RF), support vector machine, genetic algorithms, and, perhaps the most popular of all, artificial neural networks (ANN). Variants of ANN are the convolutional neural network, which uses images as input and long short-term memory for space-time prediction. Despite the wide adoption of such models for mapping, it is still unclear if interpretation of these complex models is possible, and if it could reveal the importance of the environmental covariates used as predictors. Conversely, including pedological knowledge on the soil processes into these highly empirical models is, to date, very limited. These constitute current challenges in pedometric research (Wadoux et al., 2021).

Space-time prediction

Space-time prediction is concerned with the prediction of soil properties that vary both in space and time, such as soil moisture, soil available water capacity or soil organic carbon. Space-time prediction was first developed as an extension of classical geostatistics that considers spatial variation, but non-parametric models such as machine learning models also have potential extensions for space-time prediction. Extension to space-time prediction of a soil property is a challenge because variation in space might be different from variation in time. Two approaches are usually considered to extend spatial prediction to space-time. The first adds a time dimension by mapping a spatial variable repeatedly over time. Often this approach is preferred when the temporal correlation between time steps is weak, such as when mapping short-term change in soil texture. The second approach treats time as an additional dimension to be

Fig. 6 Predicted cation exchange capacity (CEC; millimoles per kilogram) for the Edgeroi area using (A) kriging with elevation as external drift and (B) regression-kriging. Reproduced with permission from McBratney AB, Odeh IOA, Bishop TF, Dunbar MS, and Shatar TM (2000) An overview of pedometric techniques for use in soil survey. *Geoderma* **97**: 293–327.

considered. This approach is taken in space-time geostatistics by extending the methods of classical geostatistics to the space-time domain, such as the variogram. Many contributions from statisticians have been made to develop space-time variogram functions. Consider the model of spatial variation in Eq. (4), it is extended to the space-time domain by Heuvelink et al. (2017):

$$Z(s, t) = m(s, t) + Z_1(s, t) + \varepsilon(s, t), \quad (5)$$

where $Z(s, t)$ is a spatio-temporal random field, m is a space-time trend, often modelled as a function of known environmental covariates, and $Z_1(s, t)$ is a spatially and temporally dependent component usually assumed to be (multivariate) normally distributed and characterized by a covariance function. An example of variogram modelling the spatio-temporal covariance function is presented in Fig. 7. In space-time geostatistics, measurement can be repeated in time at the same spatial locations or vary between time steps. Predictions are made at unobserved locations in space and time.

Extension of machine learning models to the space-time domain is also possible but is still at the preliminary stages of academic research and has not yet reached a large audience. We expect this to change in the future with the development of new software implementations.

Fig. 7 A fitted spatio-temporal variogram using a separable function. This is the space-time extension of the spatial variogram presented in Fig. 5.

Sampling design

The sampling design used to calibrate and validate the spatial or space-time prediction models play a key role in the final accuracy. Pedometricians have contributed to the development of sampling approaches for mapping. Sampling strategies can be divided into two main approaches, namely the design- or model-based approaches (De Gruijter et al., 2006). The design-based approach relies on sampling theory where the sampling locations are selected randomly, either with simple random sampling, or by more advanced probability sampling designs such as stratified sampling. Generally, non-probability sampling approaches (i.e., model-based sampling) are more suitable for local mapping of the soil. Examples of such designs are regular grid sampling, feature space coverage or spatial coverage sampling. A method much used in digital soil mapping is conditioned Latin hypercube sampling (cLHS). Geostatistical techniques also enable sampling optimization, in which the fitted variogram and optimization algorithms enable the optimal spatial locations for mapping to be found. Much research has been done in this area, and developments along these lines are being made for machine learning. All these techniques apply for selecting the calibration sample, but it has been acknowledged that whenever possible the soil maps should be validated by independent, probability sampling (Brus et al., 2011).

Soil utility and quality

Land evaluation

Pedometrics has played a major role in advancing the role of land evaluation and, more recently, the quantification of soil quality for land management and sustainable use of land resources (Rossiter et al., 2018). Although 'soil quality assessment' is often used as a misnomer for 'land evaluation,' both could be regarded as the interpretative phase of soil survey. While land evaluation is concerned with the assessment of land performance when used for specified purposes, soil quality is defined as 'the capacity of a specific kind of soil to function, within natural or managed ecosystem boundaries, to sustain plant and animal productivity, maintain or enhance water and air quality, and support human health and habitation'. In considering productivity, environmental quality, and human health as major functions of soil, this definition requires that values be placed on specific soil functions as they relate to the overall sustainability of alternate land-use decisions. Pedometric techniques (based on 'hard' and/or fuzzy techniques) are being used to quantify soil quality and associated uncertainty. For example soil quality can be assessed in terms of requirement for different specific uses such as shown in Fig. 8. Many of the soil quality indicators are required at various scales and spatial extents in which pedometrics is playing a major role in modelling them spatially for incorporation into regional, catchment, and field-scale modeling. Another approach to soil quality analysis may be based on the concept of pedodiversity (see also previous section).

Soil functions

Pedometrics is also playing a role in quantifying and mapping soil functions. Soils provide services in terms of agricultural production, water protection and filtration, carbon storage or biodiversity habitat, among others. The ability of a soil to provide

Fig. 8 Interpolated suitability of (A) wheat, (B) sorghum and oats, and (C) dryland cotton. Based on Triantafyllis J, Ward WT, and McBratney AB (2001) Land suitability assessment in the lower Namoi Valley of Australia using a continuous model. *Australian Journal of Soil Research* 39: 273–290.

a set of ecosystem services is determined by its functions, which can be evaluated in various ways. One way is to use empirical models based on a set of indicators (i.e., basic soil properties) and combine them into soil functions. The choice of indicators is based on correlation statistics between properties, on pedological knowledge as well as on a context in which the functions will be used. Another way to model functions is to use biophysical models that better account for the soil management practices and environmental factors. In both ways, the different soil functions are interdependent since they are based on similar basic soil indicators. A change in agricultural practices to improve one function (e.g., production) can simultaneously affect other functions positively or negatively (e.g., the habitat of microorganisms). Because of these synergies and antagonisms between functions, a soil can never mobilize to its full potential each of the functions it can support. The need to study multifunctionality was the basis for the concept of soil security, or other concepts such as soil health. Converting basic properties into a product that better matches end-user demand was also the objective of land evaluation. Pedometric techniques are being used to quantify soil functions, to

account for their spatial and temporal variation and to quantify and propagate their uncertainty. For example, in Fig. 9 two maps of soil functions are shown.

Quantitative pedogenesis

As stated above, soil variability is a function of factors of soil formation. Since the publication of Jenny's state factors, pedologists have attempted to develop pedogenetic (mathematical) functions that could explain soil variability and, in many instances, predict or even simulate the soil. This has resulted in models of pedogenesis based on chemical and physical processes. The formulation of the process models and their applications depend on the scales in both the temporal and spatial dimensions. This modelling of the space-time continuum is determined by the complexity of the modelling process, which can be characterized in several ways. The first is based on computational complexity of the model, which ranges from purely qualitative (mental models) to highly quantitative, with the latter involving complex computer coding; the second is based on the complexity of the model structure, which distinguishes between mechanistic (highly complex) and empirical (simplified functional) models; and the last, but not least, is based on organizational hierarchy, which determines at which level a model is used to simulate the soil system. The hierarchical levels range from $i - 4$ (molecular-level processes) to $i + 6$ (global level). Each level is a subsystem of the level above it, therefore allowing room for upscaling.

The three characterizations above are well illustrated in Fig. 10. It should be noted that pedometrics has played a dominant role in the quantitative half of the organizational hierarchy, particularly from and above the $i - 3$ level, which is governed by material fluxes in the pores between the primary particles. Recent developments in process modelling focus on mechanistic stochastic simulations, particularly at levels $i - 3$ to i (Fig. 10) and on how the latter can be upscaled to any of the higher hierarchies.

Soil processes

Soil processes that are responsible for differentiation of the soil profile have been modeled in various ways (Stockmann et al., 2018). Soil transformation processes such as soil physical and chemical weathering are modelled through empirical chronofunctions or by mass balance models linking the chemical composition of bedrock to soil profile properties. Translocation processes such as eluviation/illuviation and soil mixing are quantified by mathematical functions based on soil textural properties. Overall, these models require considerable input of measurement data, for example radionuclide data, and have many parameters to estimate. Other problems are that these models do not provide uncertainty, and have been derived using data from soil profiles or at the pedon scale (i.e., they have scaling issue to larger area). Pedometricians have contributed to solving some of these challenges by the spatialization of soil profile process models.

Soil-landscape evolution

Process modelling has enabled the development of soil-landscape evolution models. These models are quantitative models of the short- and long-term processes of soil formation and which predict the present-day variation of soil properties. Often these models

Fig. 11 Soil formation in a landscape after 10,000 years. Reproduced with permission from Minasny B and McBratney AB (2001) A rudimentary mechanistic model for soil formation and landscape development: II. A two-dimensional model incorporating chemical weathering. *Geoderma* 103: 161–179.

are a combination of the understanding of process and empirical modelling. For example: a mechanistic pedogenetic model, based on a digital elevation model (DEM, Burrough and McDonnell, 2000), was used to simulate pedogenesis by a combination of several submodels: (1) rate of physical weathering as an exponential decline function of soil thickness; (2) rate of chemical weathering represented as a negative exponential function of both soil thickness and time; and (3) the movement of material as characterized by the diffusion transport model. The result of upscaling such an analysis is illustrated in Fig. 11, whereby, after 10,000 years, soil accumulation is predominant in the gullies compared with the ridges, where soil erodes. See also Minasny et al. (2015) for further reading (Fig. 11).

Recent research has shown that the main impediments of soil process modelling discussed above (i.e., data requirement, mechanistic understanding, number of parameters to estimate, scaling problems, uncertainty) may be tackled using statistical (data-driven) modelling, for example with state-space modelling and the space-time Kalman filter (Webster and Heuvelink, 2006). With increasing environmental concerns, the development and applications of dynamic landscape models under different land-use scenarios may well dominate pedometric research in the next few decades.

Conclusion and outlook

Stepping back in time, pedometrics appeared from a need for quantitative and digital methods in soil science and emerged from research on numerical soil classifications and geostatistical modelling of spatial variation. During the past two decades, the considerable demand for soil information has motivated pedometricians to address other soil questions from a quantitative point of view: digital soil mapping, soil monitoring, quantitative pedogenesis and soil utility, soil functions and security and to diversify the tools and techniques that they use to carry out such research: soil spectroscopy, machine learning, spatio-temporal soil inventories and quantitative process-based soil-landscape models, among others. These efforts go beyond the scope of this short introductory chapter, but were described in 2018 in a book (McBratney et al., 2018) that attempts to cover almost all aspects of pedometric research.

While pedometric research is undeniably in an expansion phase and has now many areas of application, some gaps in knowledge and challenges need to be tackled. Wadoux et al. (2021) describe 10 recent and longstanding pedometric challenges. They are classified into three aspirational categories, (i) a better understanding of soil formation, (ii) an improvement in methods for obtaining relevant digital soil data, and (iii) an improvement of our ability to address demands by soil users. These challenges show that pedometrics can contribute to many areas of soil science, and is at the interface with many questions relevant to the sustainable growth of our societies.

Abstract

Statistics embodies numerous techniques for analyzing data to discover meaning in those data against a background of variation that is of no interest, i.e., of separating signal from noise. At its heart is the notion of variance, the expected squared difference between the mean of a population and any member of it. Estimation of a variance requires replicate observations; randomization is necessary to avoid bias in estimates. Summary statistics of sets of observations comprise means, medians, variances, standard deviations and skewness coefficients. Distributions are best displayed by histograms and Q–Q plots. Analysis of variance enables investigators to estimate the effects of treatments of soil in designed experiments and the confidence they can have in their results. The analysis must match the design. The same forms of analysis can be applied to survey data in which several classes are distinguished. Relations among two or more variables are expressed by Pearson correlation coefficients calculated from measurements on those variables. The same basic calculations underlie regression in which one variable depends on one or more others and is predicted from them, and the strength of the predictions can again be assessed by analysis of variance.

Key points

- Soil varies from place to place; statistics is a technology for describing that variation quantitatively and separating signal from noise.
- Replicate sampling is required to estimate the variation in experimental material and geographic regions.
- Randomization is needed to estimate mean values and their variances, and to place confidence limits on means.
- Data can be summarized by means, medians, variances, standard deviations and skewness coefficients.
- Distributions of data are best illustrated by histograms and Q–Q plots.
- Analysis of variance apportions the variance in a set of data to sources in the designs of experiments and surveys; any actual analysis must fit the design by which the data have been obtained.
- Relations among two or more measured variables are expressed by Pearson correlation coefficients.
- A variable may be predicted from one or more others on which it depends by regression.

Introduction—Why statistics?

Soil varies from place to place at all scales from the global to the infinitesimal. Much of the variation is natural, arising from variation in its parent material and processes such as erosion and deposition on the land surface. Soil also varies from time to time as it responds to weather, plant growth, and processes in the rhizosphere engendered by that growth. Farmers have added to the variation by their enclosing, reclaiming, clearing, and fertilizing the land, though within fields they have removed some by cultivation and drainage. Further sources of variation are mineral extraction and subsequent reclamation, dumping of waste, and pollution of many kinds. Data on soil embody variation from those many sources, and the aim of statistics at its simplest is to express quantitatively that variation, to separate contributions from different sources and to describe relations.

Investigators design experiments and surveys in such a way that they can estimate the variation from particular sources such as imposed treatments or strata in a population and the differences between them. Variation in data also arises from the way observations are made; from the people who make the observations, from the imprecision of instruments, from imperfect laboratory technique, and from sampling fluctuation. One may like to think that the contributions from the laboratory are negligible, though ‘ring’ tests have often revealed them not to be so. In general, however, sampling fluctuation in the field, arising from the spatial variation there, is much the larger.

Any one measurement of a soil property is influenced by contributions from at least some of these sources. It cannot be taken as an absolutely accurate representation of the truth therefore; rather it must be seen in relation to the likely error.

Statistics are needed in soil science to estimate and express this error and to apportion it to the different sources. In this way sense (signal) can be separated from meaningless or uninteresting variation (noise) in comparisons between classes of soil, in expressing relations, in assessing the effects of treatments in experiments, and in prediction. The statistical repertoire is huge, and this article describes the basics and the fairly elementary techniques that soil scientists most often need.

The techniques can be divided into two groups, namely, description and analysis. They also have two fairly distinct fields of application: survey and experiment. In the first investigators observe and record the soil as it is on samples, and descriptive techniques tend to dominate. In the second they deliberately control some of the variation so that they can assess the effects of changes in one or a few factors that are of specific interest by analysis.

There are numerous text books on the statistics summarized in this chapter, and many more tutorial articles in scientific journals and on the World-Wide Web. I recommend strongly three: [Snedecor and Cochran \(1989\)](#), [Sokal and Rohlf \(2012\)](#) and [Welham et al. \(2015\)](#).

Population, units and samples

The soil is regarded for statistical purposes as a *population* comprising elements or *units*. The units are the bodies of soil on which measurements are made. They are more or less arbitrary and determined largely by convenience and practicality. They may be individual cores of soil, pits or pedons, each may be the volume of soil occupied by the roots of a single plant or that deformed under the wheel of a tractor, they may be pots in a greenhouse experiment, lysimeters, plots in a field experiment, or whole fields or farms. The variation among them depends very much on the size of the units; the larger they are the more variation they encompass within them and the less there is between them to be revealed in data. The size, shape, and orientation of the units, known as the “support” in survey, must be defined and adhered to throughout an investigation. The population is then all such units in a specified region or falling within some other definition for the purposes of the investigation. It is an operational definition, often known as the “target population.” In a more restricted sense the population and the units comprising it may be the values of a particular soil property in the defined supports.

Populations in surveys are typically very large, in many instances infinite, or hypothetical, and in some they are poorly defined. Measurement is feasible only on small subsets, i.e., on samples, and these subsets must properly represent their populations for the measurements to apply to the larger populations. The units in an experiment, in contrast, are typically a few dozen, though ideally the experimental material should be representative of some larger population.

Replication and randomization

Estimating the mean in a population and its associated error from measurements on a sample requires both replication and randomization. The need for replication is evident; a single value can contain no information on variation. Randomization is needed to avoid bias. At its simplest it means choosing units such that all have the same chance of being selected.

Fig. 1 Probabilistic sampling of a region; (A) simple random sampling; (B) stratified random sampling with the region divided into 25 square cells (strata) and two points per cell; (C) stratified random sampling with four mapped classes of soil as strata.

In survey selection can take the form of simple random sampling. To apply it requires (1) that each unit can be identified uniquely, and (2) a rule for the selection. Simple random sampling, as in Fig. 1A, tends to be inefficient in that it takes no account of anything known about the population beforehand, such as its spatial dependence, a soil map of the region, the relations between soil and vegetation or physiography, or the farming history. To take advantage of such knowledge the population is first stratified either into small grid cells, as in Fig. 1B, or by type of soil, vegetation, physiography, or farming as above, as in Fig. 1C. The soil is then sampled at random within each stratum independently; this is stratified random sampling, and it enables the variation due to the strata to be distinguished from variation within them.

Brus (2021) has drawn attention to a growing notion that random sampling is to be avoided where there is spatial correlation. As Brus points out, that notion is false. See also de Gruijter et al. (2006). Random sampling guarantees that estimates of means and variances are unbiased, regardless of any spatial correlation, and estimating them needs to be distinguished from mapping for which other sampling designs are more efficient. Do not be misled by publications that state otherwise; stick to the authoritative texts mentioned above and to Cochran's (1977) standard text on sampling.

In experiments treatments are allocated to the units at random. The units may be arranged completely randomly, as in Fig. 2A. In the field and greenhouse they are usually grouped into blocks such that each block contains one unit of each treatment, as in Fig. 2B; long-range variation then appears in the variation among blocks. There are many more elaborate designs.

(A)					(B)				
W	0	F	W	D	W	D	F	W	F
F	D	W	F	0	F	0	D	F	0
W	0	W	0	D	0	W	W	0	D
D	F	F	D	0	D	F	0	D	W

Fig. 2 Layout of a randomized field experiment with four treatments, 0 (control), D (dung), W (industrial waste), and F (NPK fertilizer), and fivefold replication; (A) completely randomized; (B) with the replicates arranged in five blocks.

Descriptive statistics

The mean

In almost all investigations mean values are of prime interest. Provided sampling has been properly randomized the mean of the data, denoted $\bar{z}_1, \bar{z}_2, \dots, \bar{z}_N$,

$$\bar{z} = \frac{1}{N} \sum_{i=1}^N z_i \quad (1)$$

estimates without bias the mean, μ , in the population from which the sample was drawn. How well it does so depends on the variation it embodies.

Characteristics of variation

Histogram

The variation in a set of measurements, if there are sufficient of them, can be displayed in a histogram. The scale of measurement is divided into segments of equal width, or “bins,” the values falling in each bin are counted, and bars of height proportional to the counts are drawn. Fig. 3 is an example; it summarizes graphically the way in which the frequency is distributed over the range of the data.

Fig. 3 Histograms of 434 data on available phosphorus (A) in mg L^{-1} , and (B) transformed to common logarithms. The curve in (B) is that of the fitted normal distribution, and that in (A) shows the lognormal distribution.

Variance

Variation is best expressed quantitatively as variance. For a set of N data it is the average squared difference between the observations and their mean:

$$S^2 = \frac{1}{N} \sum_{i=1}^N (z_i - \bar{z})^2 \quad (2)$$

Its square root, S , is the standard deviation, which is often preferred because it is in the same units as the measurements and is more intelligible therefore.

Ideally this variance should estimate the variance of the larger population, of which the N observations are a sample. This variance of a population is by definition

$$\sigma^2 = E[(z - \mu)^2] \quad (3)$$

where μ is mean of z in the population and E denotes expectation. Eq. (2) gives a biased result, however; S^2 is a biased estimator. The reason is that $\bar{z}$ in the equation is itself more or less in error as the estimate of μ . To remove the bias N must be replaced by $N - 1$ in the denominator:

$$s^2 = \frac{1}{N-1} \sum_{i=1}^N (z_i - \bar{z})^2 \quad (4)$$

The result, s^2 , is now unbiased, provided the sampling was unbiased in the first place.

Estimation variance, standard error and confidence

Both S and s measure the dispersion in the observations; neither expresses the reliability of the estimate of μ . The reliance one can place in an estimate of the mean can be expressed in terms of the expected squared deviation of it from the true mean, i.e., $E[(\bar{z} - \mu)^2]$. Provided that the sampling points are drawn independently of one another, as for example in simple random sampling, its estimate is derived from s^2 by

$$s^2(\bar{z}) = s^2/N \quad (5)$$

This is the estimation variance, and its square root is the standard error, which is the standard deviation of means of samples of size N . The larger is the sample the smaller is this error, other things' being equal, and the more confident we can be in the estimate. So, distinguish between the standard deviation, which describes the variation in a sample, and the standard error, which expresses the confidence associated with a mean. Standard errors should accompany means in tables compiled from replicated measurements, and they may be shown by error bars on graphs.

Eq. (5) gives the estimation variance for a simple random sample of size N . If the population has been divided into strata then s^2 , the population variance on the right hand side of the equation, can be replaced by s_w^2 , the variance within strata. The latter is generally less, often much less, than s^2 , and so stratified sampling is more precise than simple random sampling by the factor $s_{\text{random}}^2(\bar{z})/s_{\text{stratified}}^2(\bar{z})$. It also means that one can achieve the same precision with a smaller sample, and in this sense stratified sampling is more efficient. This efficiency can be expressed as $N_{\text{random}}/N_{\text{stratified}}$. The within-stratum variance, s_w^2 , can be estimated by the analysis of variance, see below.

The measures of error above represent uncertainty, which in the current context can be translated into confidence, that is the confidence we can have that a true mean, μ , deviates no more than some value from our estimate. Limits of confidence of our choosing can be obtained from the standard errors for known kinds of distribution. If the data are drawn from a normal (Gaussian) distribution and there are many of them then an interval of $2s/\sqrt{N}$ centered on $\bar{z}$ spans a symmetric confidence interval of approximately 68%. We can readily calculate wider confidence intervals by multiplying by factors, η , such as

Confidence/%	80	90	95	99
η	1.28	1.64	1.96	2.58

The factor η is the value of the standard normal deviate for the desired confidence. Evidently, the more certain, or more confident, we want to be that μ lies within some limits the wider that confidence interval must be.

When data are few ($N < 30$) the above factors need to be replaced by Student's t for the number of degrees of freedom, f . The lower and upper symmetric confidence limits about a mean $\bar{z}$ are

$$\bar{z} - t_f s / \sqrt{N} \text{ and } \bar{z} + t_f s / \sqrt{N} \quad (6)$$

Values of t are available in tables and in most statistical computer packages. For $30 < N \leq 60$ t converges to η , and for $N > 60$ the values in the above table can be used.

There are formulae for calculating the confidence limits for other theoretical distributions. In many instances, however, it is easier to transform data to approximate a normal distribution and subsequently analyze the transformed values.

Coefficient of variation

The coefficient of variation (CV) is the standard deviation divided by the mean, i.e., $s/\bar{z}$. It is often multiplied by 100 and quoted as a percentage. Its merit is that it expresses variation as pure numbers independent of the scales of measurement. It enables investigators and those reading their reports to appreciate quickly the degree of variation present and to compare one region with another and one experiment with another. It should not be used to compare variation in different variables, especially ones having different dimensions.

The coefficient is sensible only for variables measured on scales with an absolute zero. Otherwise the arbitrary choice of the zero affects it. Examples for which it should not be used are soil temperature in degrees Celsius (arbitrary zero at 273 K), color hue (which is approximately circular), and soil acidity on the pH scale (arbitrary zero equivalent to $-\log_{10}[\text{H}^+]$ with H^+ expressed in mol L^{-1}).

For some soil properties physics sets limits on the utility of the CV. For example, the minimum bulk density of the soil is determined by the physical structures that keep particles apart. Particles must touch one another, otherwise the soil collapses. For mineral soils on dry land a working minimum bulk density is around 1 g cm^{-3} . At the other end of the scale the bulk density cannot exceed the average density of the mineral particles, approximately 2.7 g cm^{-3} . So the CV of bulk density is fairly tightly constrained.

The sensible use of the coefficient of variation for comparing two variables y and z relies on the assumption that they are the same apart from some multiplying factor, b , thus:

$$y = bz \quad (7)$$

Then the mean of y is $\bar{y} = b\bar{z}$, its variance $s_y^2 = b^2 s_z^2$, and its standard deviation is $s_y = b s_z$. From there simple arithmetic shows that their CVs are the same. This principle offers a means of comparing variation with logarithms of the observations. Eq. (7) becomes

$$\log y = \log b + \log z \quad (8)$$

The logarithm $\log b$ is a constant, and so the variances, $s_{\log y}^2$ and $s_{\log z}^2$, are equal, as are their standard deviations. The resulting measure of variation is therefore independent of the original scale of measurement.

The measure can be used to compare variation in two groups of observations. Consider again soil acidity. To compare the variation in acidity of a class A with that in another, class B, we treat the hydrogen ion concentration as the original variable, transform it to pH, and compute the variances of pH. Whichever has the larger variance is the more variable, regardless of the mean. Further, we can make a formal significance test by computing $F = s_{\log y}^2 / s_{\log z}^2$ and compare the result with F for $N_y - 1$ and $N_z - 1$ degrees of freedom, see below.

Additivity of variances

Variances are additive; those from two or more independent sources in an investigation sum to the total in the data. Their square roots, the corresponding standard deviations, are not. To obtain an average variation on the original scale of measurement from several sets of data compute the arithmetic mean of their variances, weighted as appropriate by the numbers of degrees of freedom, and then take the square root of it to give an "average" or pooled standard deviation. This divided by the mean will give an "average" CV. More generally, the additive nature of variances confers great flexibility in analysis, enabling investigators to distinguish variation from two or more sources and estimate their components according to the design as by the analysis of variance.

Statistical significance

Significance in a statistical context means distinguishing a signal or the effects of some imposed treatment or detecting differences between strata against a background of "noise." It is matter of separating the variance due to the signal, treatments, or strata from that from other sources that are of no interest. The question being addressed is as follows; given the magnitudes of the several components of variance, is the signal so strong or are the differences observed so large that they are highly unlikely to have occurred by chance. If the answer is "yes," then the result is said to be significant.

A significance test is prefaced by a hypothesis. This is usually that there is no real difference between populations or treatments and that any differences among the means of observations are due to sampling fluctuation. That is the "null hypothesis," often designated H_0 , and the test is designed to reject it; *not to confirm it*. The alternative that there is a difference is denoted either H_1 or H_A .

To judge, for example, whether two means differ one computes from the sampling error the probability, P , of obtaining the observed difference if the true means were identical, assuming that one knows the form of the distribution. If P is small (conventionally <0.05) the null hypothesis is rejected, and the difference is judged significant. If P is large then the null hypothesis is likely to be correct, but we have no measure of the probability that the two means are indeed identical; instead we take the view that we have too little evidence to conclude that the difference observed applies to the population from which the sample was drawn.

One can still draw mistaken conclusions as the result of significance tests. Mistakes can be of two kinds, denoted Type I and Type II. The first occurs when we reject the null hypothesis on the basis of our sample evidence, i.e., declare a difference significant, when

the populations do not differ. The second is when we accept the null hypothesis, i.e., state that we have insufficient evidence for a difference, when the populations do differ.

One can diminish the likelihood of drawing wrong conclusions by increasing the sensitivity of the test, and that depends on the precision with which the means have been estimated, i.e., on their estimation variances or on the estimation variance of their difference. The latter is given by

$$s_{\text{diff}}^2 = \frac{s_W^2}{n_1} + \frac{s_W^2}{n_2} \quad (9)$$

where n_1 and n_2 are the numbers of observations from which the means in classes 1 and 2 derive, and s_W^2 is the variance within the classes, assumed to be common. If $n_1 = n_2$ then the variance of the difference is simply twice the estimation variance of the individual means.

Eq. (9) shows two features. One is that the larger is the variance within the populations the larger is the variance between the means and the less likely is one to establish a difference as significant. The second is that larger samples result in smaller variances and hence more sensitive comparisons. If the samples are large enough one can establish that any soil is different from almost any other for whatever property of interest.

The significance test is valuable in preventing false claims on inadequate evidence. Thus, a result might be summarized as follows.

The mean measured pH of the topsoil was 5.7 compared with 6.7 in the subsoil; but because the samples were small [or because the variances were large] the difference was not statistically significant.

However, when a difference is deemed statistically significant because the null hypothesis is rejected that does not mean that it is important or physically or biologically meaningful. For example, the difference between an observed mean pH of 5.7 in the topsoil and 5.9 in the subsoil would be of little consequence, whatever the probability of rejecting the null hypothesis. Also, while an investigator might regard a difference as significant if $P \leq 0.05$, a reader may be willing to recognize one if $P < 0.1$ or, more stringently, only if $P \leq 0.01$. The critical value of $P = 0.05$ for significance was originally suggested of R.A. Fisher; it was not a rule to be followed slavishly. Now that one can calculate probabilities so readily in computer packages professional statisticians, led by the American Statistical Association, recommend that we be guided by those values of P (Wasserstein and Lazar, 2016). If they are published instead of statements such as " $P \leq 0.05$ " along with the standard errors then readers can reach their own judgments.

Note finally that the null hypothesis is highly implausible when horizons and different types of soil are being compared; they are different.

Transformations

It is often desirable to transform data to their square roots, or logarithms or by other more elaborate functions. One reason for doing so is to obtain a new variate that approximates some known distribution, preferably normal (Gaussian) so that the usual parametric tests of significance can be applied.

The most serious departure from normality usually encountered with soil data is skewness, i.e., asymmetry, as in Fig. 3A. The normal distribution is symmetric, its mean is at its center (its mode), and the mean of the data estimates this central value without ambiguity. The mean of data from a skewed distribution does not estimate the mode, nor does the median (the central value in the data). The meaning of the statistics can be uncertain therefore. A second feature of skewed data is that the variances of subsets depend on their means. If the data are positively skewed (again the usual situation) then the variances increase with increasing mean. This is undesirable for comparisons. Third, estimation is "inefficient" where data are skewed; that is the errors are greater than they need be or, put another way, more data are required to achieve a given precision than would be if the distribution were normal. Transforming data to approximate normality overcomes these disadvantages. We achieve symmetry, and hence remove ambiguity concerning the center. We stabilize the variances. And we make estimation efficient. The second of these is perhaps the most important.

No real data are exactly normal; all deviate more or less from normality. We have therefore to decide whether to transform them. This is best done by judicious exploration of the data aided by graphic display.

Draw a histogram. If it looks symmetrical then superimpose on it a normal curve computed from the mean and variance of the data. The normal curve has the formula

$$y = \frac{1}{\sigma\sqrt{2\pi}} \exp \left\{ -\frac{(z - \mu)^2}{2\sigma^2} \right\} \quad (10)$$

where y is the probability density. Scale it to fit the histogram by multiplying by the number of observations and by the width of the bins. If the curve fits well then there is no need to transform the data.

Fig. 4 Q–Q plots of 434 data on available phosphorus (A) in mg L^{-1} , and (B) transformed to common logarithms. The points in (A) lie close to a curve, signifying strong departure from normal, whereas those in (B) lie close to a straight line characteristic of a normal distribution.

Another popular way of examining data is a Q–Q plot. This is a graph of the cumulative distribution of the data plotted against the quantiles of a standard normal distribution. If the data are approximately normal then the points lie close to a straight line. Any appreciable curve signifies strong departure from normal. Fig. 4 shows the Q–Q plots for the same data as the histograms in Fig. 3.

If the histogram is skewed then compute the skewness coefficient in addition to the mean and variance. This dimensionless quantity can be obtained via the third moment of the data about their mean:

$$\gamma_1 = \frac{1}{N S^3} \sum_{i=1}^N (z_i - \bar{z})^3 \quad (11)$$

A symmetric histogram has $\gamma_1 = 0$. Values of γ_1 greater than 0 signify positive skewness, i.e., long upper tails to the distribution and a mean that exceeds the median, which is common. Negative values of γ_1 signify negative skewness, and are unusual.

If γ_1 is positive and less than 0.5 then there should be no need to transform the data. If $0.5 < \gamma_1 \leq 1$ then it might be desirable to convert the data to their square roots; and if $\gamma_1 > 1$ then a transformation to logarithms is likely to give approximate normality.

The following example illustrates the situation. The data, which are summarized in Table 1, are 433 measurements of available phosphorus, P, in the topsoil. Their skewness coefficient is 3.95, i.e., they are strongly positively skewed, and this is apparent in their histogram, Fig. 3A. Transforming to logarithms makes the histogram, Fig. 3B more nearly symmetric, and as the skewness in the logarithms is now only 0.34; the transformation seems satisfactory. Further, the normal curve appears to fit well. Fig. 4, the Q–Q plots of the data, conveys the same message: the curve on which the points lie in Fig. 4A becomes a straight line for the transformed data in Fig. 4B.

There are statistical tests for normality, but they are unhelpful. If data are numerous then small departures from normality lead to supposed significance; if they are few the results are inconclusive.

Fig. 5 shows how the transformation stabilizes the variances. In Fig. 5A the variances of subsets of 44 from the full set of data on phosphorus are plotted against the means. Evidently, the variance increases strongly with increasing mean. Converting the data to their logarithms produces a result in which there is virtually no relation, Fig. 5B.

These simple functions change only the general form of the distribution; they do not change the detail. Normalizing the detail requires a more elaborate normal score transform.

Table 1 Summary statistics of 433 values of available phosphorus measured in a survey of topsoil.

Statistic	Scale	
	P/mg L^{-1}	$\text{Log}_{10} \text{P}$
Mean	4.86	0.546
Variance	26.52	0.1142
Standard deviation	5.15	0.338
Skewness	3.95	0.23
$\chi^2_{\text{df}18}$	368.2	26.7

Values of χ^2 , with 18 degrees of freedom, are added for the hypothesis that the data or their logarithms are from a normal distribution.

Fig. 5 Graphs of variance against mean for 10 sub-sets of 44 phosphorus data (left) on the original scale in mg L^{-1} and (right) after transformation to common logarithms.

Analysis of variance

The analysis of variance is at once one of the most powerful and elegant techniques in statistics. It and regression analysis are what may be regarded as the “bread-and-butter” of statistics in soil research. Its basis is that variances are additive and that the total variance in a population is the sum of the variances contributed by two or more sources. Working from the design of an investigation it analyzes the data by separating the contributions from those sources and estimating the variances in them. Designs vary from the simple to highly complex, but all embody the same principle.

Here we consider two of the simplest simple designs, such as appear in Fig. 2. Investigators want to know how manuring improves crop yield in the field. They have several (k) treatments, say, nothing (0), dung (D), industrial waste (W), and a complete artificial (NPK) fertilizer (F). They replicate each m times by assigning the treatments completely at random to plots of equal size. Fig. 2A shows how the experiment might be layed out with $m = 5$ replicates. They apply the treatments, grow the crop, and measure the yield at harvest, designated z .

The total variance in the yields in the experiment, s_T^2 , comprises variance from two sources, namely that between the treatments, s_B^2 , and that within them, s_W^2 , and $s_T^2 = s_B^2 + s_W^2$. The total variance is estimated by Eq. (4). The variance within any one treatment is estimated by the same formula but for only those data in that treatment. Pooling estimates for all treatments gives s_W^2 . To complete the analysis we compute also a quantity B :

$$B = \frac{1}{k-1} \sum_{i=1}^k n_i (\bar{z}_i - \bar{\bar{z}})^2 \quad (12)$$

where n_i is the number of plots in the i th treatment, $\bar{z}_i$ is the mean of the i th treatment, and $\bar{\bar{z}}$ is the general mean of the data. The computations are set out in Table 2. Finally, the analysis leads to a test of significance. We compute the ratio $F = B/W$, the distribution of which has been worked out and tabulated for degrees of freedom $k - 1$ in the numerator and $N - k$ in the denominator. If F exceeds the tabulated value at probability $P = 0.05$ (or $P = 0.01$ or $P = 0.001$, according to choice) we judge the treatments to have produced significant differences. As above, however, now that values of P can be calculated so readily we should its value for the ratio F .

In the simple experiment illustrated in Fig. 2A all n_i are equal to 5, so that n_i can be replaced by $n = 5$, and $N = mk = 5 \times 4 = 20$. Things do not always go as planned, however, and if some of the plot yields are lost then the n_i can vary from treatment to treatment, and the more general formulae in Table 2 will take care of that.

Table 2 Table for the analysis of variance for a completely randomized design with a single classification.

Source	Degrees of freedom	Sum of squares	Mean square	F
Treatments	$k - 1$	$\sum_{i=1}^k n_i (\bar{z}_i - \bar{\bar{z}})^2$	$\frac{1}{k-1} \sum_{i=1}^k n_i (\bar{z}_i - \bar{\bar{z}})^2 = B$	B/W
Residual	$N - k$	$\sum_{i=1}^k \sum_{j=1}^{n_i} (z_{ij} - \bar{z}_i)^2$	$\frac{1}{N-k} \sum_{i=1}^k \sum_{j=1}^{n_i} (z_{ij} - \bar{z}_i)^2 = W$	
Total	$N - 1$	$\sum_{i=1}^k \sum_{j=1}^{n_i} (z_{ij} - \bar{\bar{z}})^2$	$\frac{1}{N-1} \sum_{i=1}^k \sum_{j=1}^{n_i} (z_{ij} - \bar{\bar{z}})^2 = T$	

Table 3 Table for the analysis of variance for a balanced randomized block design with a single set of treatments.

Source	Degrees of freedom	Sum of squares	Mean square	F
Treatments	$k - 1$	$\sum_{i=1}^k n_i (\bar{z}_i - \bar{z})^2$	$\frac{1}{k-1} \sum_{i=1}^k n_i (\bar{z}_i - \bar{z})^2 = B$	B/W
Blocks	$m - 1$	$\sum_{l=1}^m n_l (\bar{z}_l - \bar{z})^2$	$\frac{1}{m-1} \sum_{l=1}^m n_l (\bar{z}_l - \bar{z})^2 = M$	
Residual	$(k - 1) \times (m - 1)$	$T(N - 1) - B(k - 1) - M(m - 1)$	$\frac{T(N - 1) - B(k - 1) - M(m - 1)}{(k - 1)(m - 1)} = W$	
Total	$N - 1$	$\sum_{i=1}^k \sum_{j=1}^m n_{ij} (z_{ij} - \bar{z})^2$	$\frac{1}{N-1} \sum_{i=1}^k \sum_{j=1}^m n_{ij} (z_{ij} - \bar{z})^2 = T$	

The soil might vary across the experiment systematically, so that there is trend, or in an apparently random way at a coarse scale. This variation could swell the residual variation and so mask that due to the treatments. It can be taken into account by blocking. The m replicates are now arranged in m blocks such that in each block every treatment appears once and once only. Fig. 2B shows an example in which five blocks are laid out side by side. The analysis follows the same procedure as in Table 2 except that there is an additional line for the blocks in which the sum of squares is that of deviations from the block means, as in Table 3. The residual sum of squares is diminished by this quantity, and although the residual degrees of freedom are also diminished the residual mean square, i.e., the residual variance is usually less, and the experiment more sensitive therefore.

Experiments should be planned with some hypotheses in view. The treatments should be chosen and arranged in designs to test them. The analysis that follows any experiment must fit its design; no other will do (Webster and Lark, 2018). Further, any comparisons between means should be ones that were set out at the start of the investigation; ideally they should be orthogonal to one another. The common practice of comparing all possible pairs of treatments afterwards is to be deprecated. Despite an investigator's designing an experiment well and analyzing the results in accord with nature may upset the investigator's unforeseen assumptions. Webster and Lark (2019) guide readers on what to do in those circumstances by transformations of the data.

In soil survey different classes of soil replace treatments—see Webster and Lark (2013). In the simplest cases each class is sampled at random, and the n_i are rarely equal, either because it is difficult to obtain equal representation or because we deliberately sample in proportion to area so as to maintain a fairly constant sampling density. Effectively the classes are weighted in proportion to the areas they cover. We can still compute $F = B/W$ and test for significance, but as above this is less interesting than the differences between the means.

The variance between treatments or classes, s_B^2 , can be obtained from B . The latter combines variation both from between treatments or classes and within them:

$$B = ns_B^2 + s_W^2 \quad (13)$$

if $n_i = n$ for all i . Rearranging then gives

$$s_B^2 = (B - s_W^2)/n \quad (14)$$

If the n_i are unequal then n is replaced by n^* , given by

$$n^* = \frac{1}{k-1} \left(N - \frac{\sum_{i=1}^k n_i^2}{N} \right) \quad (15)$$

and

$$s_B^2 = (B - s_W^2)/n^* \quad (16)$$

Fixed effects, random effects and intra-class correlation

The value s_B^2 obtained as above estimates $\sum_{i=1}^k (\mu_i - \mu)^2 / (k - 1)$, where μ_i is the expected value of treatment or class i , and μ is the expected value in the whole population. In designed experiments, in which the effects are fixed by the experimenter, it is of little interest. In soil survey, however, where it is often a matter of chance which classes are actually sampled, the differences $\mu_i - \mu$ are subject to random fluctuation. In this event s_B^2 estimates the variance, σ_B^2 , among a larger population of means and is termed a component of variance, and it is of considerable interest.

The between-class variance expressed as a proportion of the total variance, $\sigma_B^2 + \sigma_W^2$, is the intraclass correlation, ρ_i :

$$\rho_i = \frac{\sigma_B^2}{\sigma_B^2 + \sigma_W^2} \quad (17)$$

which is estimated from the analysis variance table by

$$r_i = \frac{s_B^2}{s_B^2 + s_W^2} = \frac{B - W}{B + (n * -1)W} \quad (18)$$

The intra-class correlation has a theoretical maximum of 1 when every class is uniform. In practice there is always some variation within classes, and so ρ_i never attains 1. The minimum of ρ_i is zero, when $s_W^2 = 0$. The calculated estimate of ρ_i can be negative, because $B < W$, and is usually best explained by sampling fluctuation.

Covariance, correlation and regression

The relations between two variables can be expressed by correlation and regression.

Covariance

The covariance of a pair of variables, y and z , is estimated from data in a way analogous to the estimation of the variance, Eq. (4), by

$$\hat{c}_{y,z} = \frac{1}{N-1} \sum_{i=1}^N \{y_i - \bar{y}\} \{z_i - \bar{z}\} \quad (19)$$

where $\bar{y}$ and $\bar{z}$ are the means of y and z respectively. It is not easy to envisage, especially if y and z have different dimensions. The relation may be standardized by its conversion to correlation, below.

Correlation

The correlation between two variables, strictly the linear correlation, or the product-moment coefficient of linear correlation, is a dimensionless quantity, usually denoted by ρ for the population parameter. Its estimate, r , is obtained from the covariance by

$$r_{y,z} = \frac{\hat{c}_{y,z}}{\sqrt{s_y^2 s_z^2}} \quad (20)$$

s_y^2 and s_z^2 are the estimated variances of y and z . It was proposed by Karl Pearson, and for that reason it is often called the Pearson correlation coefficient.

The coefficient is effectively a standardized version of the covariance. It measures the extent to which the data when plotted as one variable against the other in a scatter graph depart from a straight line; see Fig. 6. It may vary between +1, signifying perfect positive correlation, and -1 for perfect negative correlation. Intermediate values indicate departures from the straight line, as in Fig. 6, for which $r = 0.699$. In general positive values of r indicate the tendency of y and z to increase together, whereas negative values arise when y increases as z decreases. A value of 0 represents no linear relation.

Notice that the statistic refers specifically to linear correlation. The relation between two variables might be curved; the absolute value of r would then be necessarily less than 1 regardless of any scatter about the curve.

When the data, $y_i, z_i, i = 1, 2, \dots, N$, are from a sample then $c_{y,z}$ and $r_{y,z}$ estimate corresponding population parameters, $\text{cov}_{y,z}$ and $\rho_{y,z}$. If the data can be assumed to be drawn from a bivariate normal distribution then one can test r for significance. One computes Student's t with $N - 2$ degrees of freedom:

$$t_{N-2} = \frac{r\sqrt{N-2}}{\sqrt{1-r^2}} \quad (21)$$

The probability of this value's occurring on the null hypothesis that $\rho = 0$ can then be computed or looked up in a table of t .

Spearman rank correlation

Where the distributions of the underlying variables are far from normal the Pearson coefficient can be replaced by Spearman's rank correlation coefficient, usually denoted r_s . The values of each variable are ranked from smallest to largest and given new values $1, 2, \dots, N$. The correlation coefficient is then computed by applying Eqs. (19) and (20). Alternatively, one may take the differences, $d_i, i = 1, 2, \dots, N$, between the ranks and compute

$$r_s = 1 - \frac{6 \sum_{i=1}^N d_i^2}{N(N^2 - 1)} \quad (22)$$

Many soil variables observed in the field, such as grade of structure and frequency of mottles, are recorded as rankings rather than measured. In these circumstances the correlations between them can be expressed by the Spearman coefficient, whereas

Fig. 6 Scatter graph showing the relations between two variables Y and Z for which the correlation coefficient, r , is 0.699. The symbols are the observed values, the solid line, labeled P , is the principal axis with gradient 0.844, equivalent to an angle of 40.1° to the horizontal. The dashed line (---) shows the regression of Y on Z with gradient $b_{Y,Z} = 0.621$, and the dotted line (....) shows that of Z on Y , for which $b_{Z,Y} = 0.788$, giving it a gradient in the figure of $1/b_{Z,Y} = 1.269$.

the Pearson coefficient would be inappropriate. Also in these circumstances tied ranks in any large set of data are inevitable, and Eq. (22) must be elaborated. The coefficient can be calculated in various ways, but from Eqs. (19), (20) and (22) we can derive

$$r_s = \frac{\sum_{i=1}^N (y_i - \bar{y})^2 - \sum_{i=1}^N T_{i,y} + \sum_{i=1}^N (z_i - \bar{z})^2 - \sum_{i=1}^N T_{i,z} - \sum_{i=1}^N d^2}{2\sqrt{\left\{ (y_i - \bar{y})^2 - \sum_{i=1}^N T_{i,y} \right\} \left\{ (z_i - \bar{z})^2 - \sum_{i=1}^N T_{i,z} \right\}}} \quad (23)$$

in which

$$T_i = \frac{t_i(t_i^2 - 1)}{12} \quad (24)$$

where t_i is the number of observations tied at rank i .

For small samples r_s is somewhat less sensitive than the Pearson coefficient in that larger values are necessary to establish statistical significance.

Regression

Regression, which is dealt with comprehensively by Draper and Smith (1981), treats the relation between two variables in a somewhat different way by designating one of them, y , as depending on the other, z , represented by the equation:

$$y = \beta_0 + \beta_1 z \quad (25)$$

The underlying rationale is often physical. For example, we may wish to discover how the soil's strength is changed by additions of gypsum. We could add known amounts of gypsum to the soil, measure the resultant changes in strength, and from the data estimate by how much on average the strength is changed by each increment in gypsum added. We adopt the Gauss linear model for the purpose:

$$y_i = \beta_0 + \beta_1 z_i + \varepsilon_i \quad (26)$$

where y_i is the value of the random dependent variable, Y , here strength, in unit i , z_i is that of the independent variable, gypsum added, and ε_i is random error term that is uniformly and independently distributed with variance σ_ε^2 . The quantities β_0 and β_1 are parameters of the model and are estimated as follows:

$$\hat{\beta}_1 = \frac{\hat{c}_{y,z}}{s_z^2} \quad (27)$$

and

$$\hat{\beta}_0 = \bar{y} - \hat{\beta}_1 \bar{z} \quad (28)$$

Eq. (27) gives the rate at which strength changes in response to increments in gypsum. The quantity $\hat{\beta}_0$ in Eq. (28) is the intercept at $y = 0$ and is likely to be of subsidiary interest. Together they may be inserted into Eq. (25) for predicting unknown values of Y if we know those of z :

$$\hat{y} = \hat{\beta}_0 + \hat{\beta}_{1z} \quad (29)$$

The procedure minimizes the sum of the squares of the differences between the measured values y_i ; $i = 1, 2, \dots, N$, and those expected from Eq. (25), $\hat{y}_i$:

$$s_{y,z}^2 = \frac{1}{N-2} \sum_{i=1}^N (y_i - \hat{y}_i)^2 \quad (30)$$

A somewhat different situation is common in soil survey. In it we sample the soil without knowing in advance what values we shall obtain for the variables of interest. For example, we may measure both cation exchange capacity, CEC, and clay content, and we may regard CEC as depending in a physical sense on clay content. The data on both variables now contain random components, and for this reason we designate them with the capital letters, Y and Z , respectively. We may express the relation as the regression of CEC on clay and estimate the parameters in the same way as for the Gauss linear model. In doing so we assign all the error to CEC and minimize the sum of squares, $s_{y,z}^2$, as in Eq. (30). The purpose is now prediction, i.e., prediction of CEC, knowing the clay content. We could equally well compute the regression of clay on CEC. The roles of Y and Z are reversed, and we minimize

$$s_{z,y}^2 = \frac{1}{N-2} \sum_{i=1}^N (z_i - \hat{z}_i)^2 \quad (31)$$

where

$$\hat{z} = \hat{\beta}'_0 + \hat{\beta}'_{1y} y \quad (32)$$

The primes attached to β'_0 and β'_{1y} signify that these quantities refer to the regression of Z on Y and that they are different from those for the regression of Y on Z . In other words, the line defined by Eq. (29) differs from that defined by Eq. (32), as Fig. 5 shows.

The correct line to choose depends on which variable is to be predicted. To predict y from z use Eq. (29); to predict z from y use Eq. (32).

Further matter

Research into the soil and modern developments in instrumentation are leading to ever more advanced statistical understanding and technique. In recent years pedologists have mastered the theory of regionalized variables to model and map spatially correlated soil variables using geostatistics; see the chapter on this topic. Soil biologists are measuring numerous properties of the soil's microora and its genetics and are analyzing the data by various multivariate techniques to identify relations, to group organisms and their functions. Multivariate analysis is also treated as a topic in the encyclopedia. Sensing in the visible and infrared parts of the electromagnetic spectrum, from the air and satellites, from close to the soil surface (proximal sensing) and in the laboratory is producing huge quantities of multivariate data, much of which is redundant. Techniques, including machine-learning, have been developed to compress and smooth the spectral data and extract features that have mineralogical, chemical and biological meaning, and to predict properties that are much more time-consuming and expensive to measure by earlier conventional methods. Machine learning is covered in another chapter. Note, however, that these techniques do not replace or invalidate the sound experimental design, random sampling and the appropriate analysis of the data thereby obtained.

Abstract

With the growing surplus of data available for modelling in soil science, multivariate analyses offer a path to understand the patterns in large datasets with 100s or 1000s of variables. In this chapter, we explore three classes of multivariate techniques and analysis, and a case study using one technique for each class: dimension reduction with principal component analysis (PCA), supervised classification with linear discriminant analysis (LDA) and unsupervised classification with *k*-means clustering. While by no means comprehensive, we demonstrate potential uses for multivariate analysis in soil in agricultural and ecological contexts. In addition, we provide some examples of alternatives for each of the classes.

Key points

- Multivariate analyses are increasingly needed by soil scientists due to the increasing ease of data collection.
- Principal component analysis can be used for dimension reduction to simplify spectral data or a datasets with many variables and nullify multicollinearity.
- Discriminant analysis is used for supervised classification to differentiate soil orders or soil types.
- *k*-means clustering is a form of unsupervised classification commonly used to group or partition soil spectra in libraries, or similar types of soil which enables stratified soil sampling.

Introduction

We live in an age where it has never been easier to measure properties on a soil sample, whether in the field or in the laboratory. For example, routine wet chemistry-based laboratory testing of soil for agronomic purposes can generate reports outlining well over 10 soil properties for consideration. This can be further accentuated with soil spectroscopy in a field or laboratory setting with technologies such as visible near-infrared (vis-NIR) spectroscopy that generate 100s of spectral measurements at very fine wavelengths (Fig. 1). More recently, advances in soil biological analysis have made it possible to generate 1000s of DNA measurements based on soil microbes.

Fig. 1 An example of soil spectral vis-NIR measurements for 480 soil samples.

All of these data can be generated from one soil sample, but in many cases data are collected at depth and spatially, further increasing the amount of data that are available for analysis and interpretation from one study area. In the spatial context there is also the increase in readily available geospatial datasets, which can be related to soil. Key examples using these in spatial soil studies are digital terrain and remote sensing data. Nowadays, these datasets are free and openly available to the public for most of the globe. Key examples include a global digital elevation model (DEM) from a Shuttle Mission in 1999 and more recently the Copernicus Programme DEM, as well as the Landsat and Sentinel remote sensing products. From one digital elevation model, 10 or more terrain attributes can be generated to represent soil variation. The same is true for remote sensing data, which have individual bands but also spectral indices such as the normalized difference vegetation index (NDVI) that can be used. This means once again for each satellite product we can have 10 or more attributes available for analysis.

For the results from conventional wet chemistry laboratory analysis, it is relatively easy to interpret the measurements. The situation becomes more abstract, however, when trying to find meaning, relationships and patterns in datasets such as soil reflectance obtained from vis-NIR spectroscopic measurements due to both the size of the dataset and because the measurement is not directly related to one soil property only. The same difficulty exists when trying to relate terrain attributes or remote sensing measurements to soil properties. This is where multivariate analysis can be useful as a way to understand patterns in large multivariate soil datasets by reducing the number of variables in what is called dimension reduction and also for grouping samples together in what is called classification.

In many cases the soil scientist wishes to go beyond exploratory data analysis and aims to build some sort of predictive model; two examples are soil spectral inference and digital soil mapping. In soil spectral inference the starting point could be 200+ bands per sample to create a model. In digital soil mapping we can easily start with 40+ predictors to consider when designing a sampling scheme or building a spatial model. Not all of the data are useful for understanding the soil condition and variability, and while simple correlation analysis is useful, as the number of variables increases it becomes more difficult to identify useful patterns and variables, especially as many are correlated. In these cases, it is important to select useful features from the dataset, which is where dimension reduction techniques are advantageous and the model builder has fewer variables to consider, and each is independent of the other.

In this chapter we present key multivariate methods of analysis that focus on three general approaches:

- 1) dimension reduction, where the soil scientist aims to simplify a multivariate dataset of (most likely) correlated variables to a small set of variables, all of which are independent;
- 2) unsupervised classification, where the soil scientist aims to group multivariate observations into groups of strong similarity but does not have a variable such as soil type that can act as a natural grouping variable;
- 3) supervised classification, where the soil scientist has a variable such as soil type that can act as a natural grouping variable but aims to build a classification model based on a set of predictor variables that are typically easier to acquire than the grouping variable.

For each approach we present the basic theory and examples of applications from the literature, and also analysis with a soil dataset to illustrate the practical implementation of the method. We conclude each section with commentary about less used multivariate methods that may be useful for soil scientists.

Dimension reduction

Principal components

Theory

Principal component analysis (PCA) is generally used as an ordination technique in exploratory data analysis, but can be used to make decisions in predictive models. One common use for PCA is when predictors are strongly correlated, which can cause issues of multicollinearity if modelled. Principal component analysis can be used to transform the set of x correlated continuous variables over y samples to a set of p uncorrelated variables over the same samples.

The variables are standardized before deriving a covariance matrix, from which eigenvectors and their corresponding eigenvalues are then calculated. The eigenvectors are the directions of the axes, and the eigenvalues are the coefficients that reflect the proportion of the total variance each axis explains. A PCA involves rotating the original axes of the data to maximize the variance in the dataset. The data projected on to the new, rotated axes are principal component (PC) scores, and each dimension is an uncorrelated variable or PC. The first PC has the largest eigenvalue and explains the most variance, and each subsequent coordinate is orthogonal or perpendicular (i.e. uncorrelated) to the last. Thus, the most informative PC is the first, and the least informative is the last. As such, less informative PCs can be culled according to a scree test (Fig. 2), resulting in dimension reduction. The first few PCs combine and compress the information of all the variables, albeit at the expense of the interpretability of each predictor to the prediction of the response variable.

Principal component analysis does not require statistically normal data, though outliers and missing data should be removed, or substituted with the mean or median value of a variable to ensure sufficient data remain for analysis. The assumptions for PCA are relatively easily met. The first assumption, often called sphericity, requires the variables to have some degree of correlation for the analysis to be useful. This assumption is true if the problem of multicollinearity is the reason for performing PCA. The second assumption is that there should be an adequate number of samples per variable to ensure reliable and stable results, and many multivariate textbooks cite a 20:1 ratio. In the age of big data, multivariate datasets are often substantial and meeting this assumption is not a problem. The third assumption is that the determinant of the correlation matrix must be positive. In general it means that there should be unpredictability in the data such that it cannot be exactly predicted in the linear combination of variables. This assumption is rarely tested since failure to meet this assumption will result in failure to compute PCs, leading to an error.

Application

In the following example, we analyzed soil samples from various sites across The University of Sydney farm *L'lara*, an 1850 ha mixed farming property with Gray or Brown Vertosols (Isbell, 2016) in northern New South Wales (NSW), Australia. The farm was sampled in three separate campaigns in July 2017, July 2018, and August 2019 (Llara 1–3); Filippi et al. (2019) describe the earlier

Fig. 2 Elbow or scree plot of the eigenvalues of the first 20 principal components.

Table 1 List of publicly available national datasets and proximally sensed imagery available for The University of Sydney farm L'lara, NSW, Australia.

Dataset	Data Source	Resolution	Term
Terrain Attributes	CSIRO Data Portal (Gallant and Austin, 2015)	30 m	Digital elevation model (DEM_30), aspect, multi-res ridge top flatness, multi-res valley bottom flatness, slope percent, plan curvature, profile curvature, slope in degrees (SlopeDeg), slope in percent, slope relief, topographic position index, total wetness index
Radiometrics	Geoscience Australia (Minty et al., 2009)	100 m	Radiation adsorbed dose; gamma radiometric potassium (K) (rad_k), uranium (U), thorium (Th), Th:K, U:Th ratio, U ² :Th ratio and U:K ratio
Weather	CSIRO Data Portal (Xu and Hutchinson, 2011)	30 m	ANUCLIM annual mean temperature 1976–2005, ANUCLIM annual mean rainfall 1976–2005
Satellite Imagery	USGS (Landsat 7)	30 m	2000–2020 normalized difference vegetation index percentiles (NDVI_5, NDVI_50, NDVI_95)
Other	Gray et al. (2016)	100 m	Silica index
Proximal Sensing Imagery		5 m	Gamma radiometrics potassium (gamma_k), apparent electrical conductivity (EM)

The abbreviations given are used in Fig. 3.

dataset and Jones et al. (2021) the later ones. The dataset also includes a range of proximally sensed as well as national and publicly available predictor variables, listed in Table 1.

A total of 27 numerical predictors were extracted for the L'lara dataset (Table 1). Taking its size into account, this dataset contains too many predictors for a regression model and could cause model overfitting. In addition, a correlation matrix of these predictors had multiple Pearson correlations above 0.80, namely the gamma radiometrics with their respective ratios, and the national and proximally sensed gamma radiometrics.

After applying a PCA on all 27 predictors, the subsequent PCs were uncorrelated with each other. There were, however, still 27 PCs and there are several methods to determine how many PCs to keep or discard.

An elbow or scree plot (Fig. 2) of the eigenvalues of each PC can be used to determine the number of PCs to keep. In this case the eigenvalues, or explained variances, are small for the 10th PC onward (i.e. the forearm of the curve) and would offer minimal additional value to a model.

A less subjective selection process is to retain all PCs with an eigenvalue above 1 (Kaiser's Criterion), which in this case includes the first 7 PCs. This is because an eigenvalue greater than 1 accounts for more than one variable's amount of variance. Another approach is to set a threshold of cumulative variance percent, commonly 75%, 80% or 90%, and select the number of PCs to retain accordingly. In this case keeping the first 11 PCs explains 92% of the total variance in the predictors, and a further reduction to 7 PCs retains 80% variance and 6 PCs retains 75%. Even with a conservative approach, a dimension reduction of 27–11 predictors can be carried out with PCA, while maintaining 90% of the total predictor variance.

Principal component analysis can also be used as a standalone data exploration technique. Three separate sampling campaigns were conducted for the L'lara farm property. Llara 1 and Llara 2 samples were taken from cropped land only, whereas the scope of the Llara 3 sampling campaign also covered grazing land. By conducting a PCA analysis, we can also determine whether the locations of each sampling campaign were covered by a similar range of values for the numerous predictor variables, or predictor variable space. This is important for cases where we wish to use one dataset for developing a spatial model and another for validating the spatial model independently; this determines the occurrence, or to some degree, the extent of extrapolation. We therefore need to ensure that we are testing the model in its appropriate prediction domain.

For this example, a simpler set of 6 predictor variables (labeled in Fig. 3) was analyzed with PCA. The first 3 PCs explained over 90% of the cumulative variance of the variables. Fig. 3 is a biplot which shows the scores for PC1 and PC3 as points and the 95% confidence interval for each sampling campaign's group centroid as ellipses. Overlapping ellipses indicate the samples from the Llara 1 and 2 campaigns (red and green in Fig. 3, respectively) were covered by roughly the same covariate space, whereas Llara 3 (seen in blue in Fig. 3) had a wider attribute space. This suggests if the Llara 3 dataset is used for independent validation, it could result in extrapolation beyond what the model is capable of. Poor data splitting for validation is a common issue in large scale spatial modelling, which can be identified with a PCA.

Overall, PCA is a flexible data exploration technique that can be used to counter multicollinearity, achieve dimension reduction and compare datasets in terms of the attribute space they cover. There are countless ways to use the output of the analysis to observe trends, clusters and outliers.

An alternative

An alternative to PCA is non-metric multidimensional scaling (nMDS) which produces an ordination based on a distance or dissimilarity matrix. Unlike methods which attempt to maximize the variance between objects in an ordination (e.g. as in PCA), nMDS attempts to represent, as closely as possible, the pairwise dissimilarity between objects in a reduced-dimensional space. It is also a rank-based approach (hence non-metric). This means that the original distance data are transformed into rank data. It also means that information about the magnitude of distances between objects is no longer available, but as a rank-based technique, it is robust for non-linear data or data with any statistical distribution, i.e. no assumptions about the data are necessary. It can (1) tolerate missing pairwise distances, (2) be applied to a (dis)similarity matrix formed with any (dis)similarity measure and (3) use quantitative, semi-quantitative, qualitative, or mixed variables. The output of nMDS, sample scores, can be visualized with a biplot, similar to PCA, to highlight patterns between variables.

Fig. 3 Biplot of PC1 and PC3 grouped by sampling campaigns on The University of Sydney farm L'lara, NSW, Australia. The ellipses are the boundaries of the 95% confidence interval for each campaign. Descriptions for variables are in Table 1.

Supervised classification

Linear discriminant analysis

Theory

Soil scientists may be interested in identifying soil attributes that best explain differences between two soil classes or entities, or the environmental factors that explain the patterns of distribution of soil classes. In this case, the interest relies on explaining differences between well-defined classes. On the other hand, we may be interested in assigning or predicting the membership of an individual (e.g., soil profile or soil sample) of unknown membership into a predefined group. Discriminant analysis can be used for dimension reduction, descriptive analysis or classification, but here we emphasize its use for classification.

Linear discriminant analysis (LDA) is a generalization of 'Fisher's linear discriminant functions' (Fisher, 1936). Fisher formulated discriminant functions as linear functions of attributes that best discriminate individuals from two different populations or two classes. The discriminant functions can be represented as:

$$\mathbf{X} = a_1 \mathbf{x}_1 + a_2 \mathbf{x}_2 + \dots + a_d \mathbf{x}_d \quad (1)$$

Where $\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \dots, \mathbf{x}_d$ are measurements of d attributes or features across the total number of individuals, and $a_1, a_2, a_3, \dots, a_d$ are the coefficients of the linear functions. The coefficients of the linear functions maximize the ratio of the difference between the class means (class centroid) to the standard deviation within the class, that is, the between-class sum of squares to the within-class sum of squares. In the two-class case, we begin by computing the mean of each class, $\bar{\mathbf{x}}_1$ and $\bar{\mathbf{x}}_2$. Then, the between-class scatter matrix is calculated as $\mathbf{S}_B = (\bar{\mathbf{x}}_2 - \bar{\mathbf{x}}_1)(\bar{\mathbf{x}}_2 - \bar{\mathbf{x}}_1)^T$, and also the within-class scatter matrix $\mathbf{S}_W$:

$$\mathbf{S}_W = \sum_{i \in C_1} (\mathbf{x}_i - \bar{\mathbf{x}}_1)(\mathbf{x}_i - \bar{\mathbf{x}}_1)^T + \sum_{i \in C_2} (\mathbf{x}_i - \bar{\mathbf{x}}_2)(\mathbf{x}_i - \bar{\mathbf{x}}_2)^T, \quad (2)$$

where C_1 and C_2 are classes 1 and 2 respectively. The solution to the coefficients is found by maximizing the quotient between the between-class variance to the within-class variance:

$$J(\mathbf{a}) = \frac{\mathbf{a}^T \mathbf{S}_B \mathbf{a}}{\mathbf{a}^T \mathbf{S}_W \mathbf{a}}, \quad (3)$$

which leads to

$$\mathbf{a} = \mathbf{S}_W^{-1} (\bar{\mathbf{x}}_1 - \bar{\mathbf{x}}_2). \quad (4)$$

Rao (1948) generalized the method for multiple classes ($k > 2$) using $k-1$ discriminant functions. As with MANOVA (multivariate analysis of variance), there are some assumptions concerning the data for performing LDA: (1) the independent variables must have

a normal distribution at each class level (multivariate normality), and (2) the multiple variance-covariance matrices are homogeneous (homoscedasticity). The equality of covariances is commonly tested with Box's M test (*F*-ratio test) (Box, 1949) or a similar multivariate test of equal group dispersions. When the covariances are not considered equal, quadratic discriminant analysis can be used in place of LDA. Another limitation of LDA is that it does not handle collinearity of predictor variables well, but a dimension reduction technique like PCA can be used as a preliminary step to create latent independent variables.

Samples for classification LDA should represent a single random sample or a mixture of two or more populations (classes), or several independent, random samples of two or more populations (McGarigal et al., 2013). The ideal sample size will depend on the homogeneity of the soils and soil properties, so that the dispersion is estimated accurately. The minimum rule is that there should be at least two more observations than predictor variables, and at least two observations per class. Williams and Titus (1988) recommended several observations per group, at least three times the number of predictor variables.

Application

The first application of discriminant analysis in soil science was by Cox and Martin (1937), who used it to find the relevant soil properties for predicting the presence of *Azotobacter* in the soil. Oertel (1961) developed Fisher's discriminant functions to allocate soil profiles into either one of two soil classes. Several studies applied discriminant analysis to establish and test differences between soil classes (Hughes and Lindley, 1955) or allocate soil profile observations into predefined soil classes in soil survey studies (Webster and Burrough, 1974). Linear discriminant analysis is often used as a classification model for digital soil mapping (Sun et al., 2011). Soil spectral data (e.g., vis-NIR) are also used as independent variables for discriminating soil types (Lazaar et al., 2019). In chemometrics, LDA can be applied for validating the forensic classification of soil samples, as a tool in forensic soil science for linking evidence to crime scenes (Lee et al., 2012). Canonical variate analysis, or multiple discriminant analysis, has been applied to discriminate the legacy of vegetation and land use on soils using soil near-infrared (NIR) (Ertlen et al., 2015) and mid-infrared (MIR) spectral data (Dudek et al., 2021).

Forest species influence the quantity and chemical composition of the organic matter that enters the soil, which in interaction with environmental factors and the microbial community, and the successive transformations of soil organic matter may lead to distinctive spectral signatures of forest species. In the following example, we use data from Román Dobarco et al. (2021a) to test whether LDA can differentiate and predict the overstory species for the origin of the soil organic matter.

The dataset consists of 70 spectra of soils sampled at 0–15 cm depth beneath trembling aspen (*Populus tremuloides* Michx.) ($n = 27$), mixed ($n = 23$) and conifer (*Abies lasiocarpa* (Hook.) Nutt. and *Pseudotsuga menziesii* (Mirbel) Franco) ($n = 20$) stands. Soil samples were subject to fractionation to separate soil organic carbon associated with mineral particles in the fine fraction ($<53 \mu\text{m}$), and a light fraction (LF) (Román Dobarco et al., 2021a). The LF is predominantly composed of free and intra-aggregate particulate organic matter, consisting mainly of partly decomposed plant material. The LF samples were scanned with Fourier transform infrared spectroscopy in the MIR range ($4000\text{--}500 \text{ cm}^{-1}$). A scaled PCA was first applied to remove the multicollinearity from the spectral data, and the scores of the first 6 principal components that explain 96% of the variance were used as predictor variables.

The LDA had an overall accuracy of 63% and a kappa statistic of 0.43, which indicates some agreement between predictions and observations. In the confusion matrix (Table 2) we observe that most of the misclassified aspen LF samples were assigned to the mixed class ($n = 6$). The user's accuracy was similar for aspen and conifer (67%), indicating that the probability of the predictions for representing the real class was reasonably acceptable for these two classes. Mixed LF had the lowest user's and producer's accuracy, suggesting that the chemistry of the LF under mixed canopies may too heterogeneous and variable to discriminate from the other two classes, or too similar to the LF of aspen and conifer as it originates from both vegetation types (Fig. 3). User's accuracy refers to the probability that a prediction from the LDA model represents that category, or a measure of commission error. It is calculated as the total number of correct predictions of a class divided by the total number of predictions in that category (e.g., 12 predicted and observed mixed/22 predicted mixed). Producer's accuracy is calculated as the total number of correct predictions of a class divided by the total number of observations of that class and indicates the probability of an observation being correctly classified, or a measure of omission error (e.g., 12 predicted and observed conifer/20 observed conifer). The LDA model did not completely succeed in distinguishing the forest species that contributed to the LF (Fig. 3), suggesting that despite initial differences between the chemical composition of aspen litter and conifer needles, microbial activity and site differences (e.g., microclimate, soil dominant mineralogy and soil type) had caused some convergence in the chemistry of the LF at that stage of decomposition.

Table 2 Confusion matrix with the results of a LDA for classification of forest species-derived light fraction.

		Observed			Total	User's Accuracy (%)
		Aspen	Mixed	Conifer		
Predicted	Aspen	20	6	4	30	67
	Mixed	6	12	4	22	55
	Conifer	1	5	12	18	67
	Total	27	23	20	70	
	Producer's Accuracy (%)	74	52	60		

An alternative

Here, we have presented LDA as a supervised classification problem but there are many alternatives that can be used, especially with the easily accessible data science tools available to the modern soil scientist (multiple platforms and software for data storage, querying, analysis and visualization). One example is random forests, which are based on a forest of decision trees, and unlike LDA are non-parametric methods. Decision trees can be used for continuous outcomes called regression trees or categorical outcomes, called classification trees. As a whole, they are called classification and regression tree (CART) models. As techniques, they are easy to use and interpret, but their power becomes evident when they are used in ensemble models, such as bagged (bootstrap aggregating) trees and random forests. Compared to LDA, they are particularly useful when the relation between the response and predictor variables is complex, and includes non-linearities and interactions between predictors. For a classification problem it is best to compare different methods for a particular study.

Unsupervised classification

k-means clustering

Multivariate hard *k*-means clustering is a common technique implemented in soil science. This approach is used to allocate samples or data into groups based on their characteristics. Samples within each group are based on having similar characteristics. One common example of applying *k*-means clustering is to create spatial zones of similarity across a study area, such as an agricultural field, or a hydrological catchment or watershed. Another common example is in the field of soil spectroscopy, where soil samples are grouped based on their spectral reflectance derived from sensors such as vis-NIR, and MIR.

Theory

The *k*-means is a hard cluster algorithm that partitions data points into clusters, where data points in each cluster are more similar to each other than data points in different clusters (MacQueen, 1967). It uses the clustering error criterion, which calculates the squared distance for each point from the cluster center, and then sums these distances for all points in the data set (Likas et al., 2003). The goal of the objective function is to minimize the sum of squares error of the Euclidean distance over all data points (Heil et al., 2019).

If a random point is $\mathbf{x}_i = (x_1, x_2)$ and the initial cluster center is $\mathbf{c}_i = (c_1, c_2)$, then the Euclidean distance between the point and cluster center, $d(\mathbf{x}_i, \mathbf{c}_i)$, can be given by;

$$d(\mathbf{x}_i, \mathbf{c}_i) = \sqrt{(c_1 - x_1)^2 + (c_2 - x_2)^2}. \quad (5)$$

The cluster center, $\mathbf{c}_i$, assigned to a set of points is recalculated after points are reassigned to clusters by the minimum sum of squares error distance. The algorithm continues until this is minimized for a particular number of clusters.

The *k*-means clustering requires that a specific number of clusters to be created is specified (Román Dobarco et al., 2021b). A common way to select this is the 'elbow method'. In this approach, the optimal number of clusters is indicated by the turning point in the curve of total within-cluster sum of squared errors (WCSS) with regard to the number of clusters, after which the marginal effect on decreasing the WCSS with an increasing number of classes is minor (Han et al., 2012).

Applications

Spectroscopy

One common application of *k*-means clustering in soil science is to partition samples based on their spectral information, such as from vis-NIR or MIR sensors. Because soil spectral information can be recorded cost-effectively and rapidly, spectral libraries can cover very large areas, encompassing soils with very different characteristics (Heil et al., 2019). These large soil spectral libraries are often complex and have many non-linear relationships (Araújo et al., 2014). This is a challenge, and classification algorithms such as *k*-means can be applied to identify subsets or patterns of similar samples prior to further analysis (Heil et al., 2019). Partitioning soil samples into smaller subsets based on spectra can significantly improve model predictions (Heil et al., 2019). A study by Araújo et al. (2014) found that the division of a large vis-NIR soil spectral library into clusters substantially reduced errors and improved model predictions of clay and organic matter. This is because clustering divided the global dataset into more mineralogically uniform clusters, regardless of the geographical origin of samples. These results clearly demonstrate the value of clustering soil spectral data into subsets compared to using large global spectral libraries (Araújo et al., 2014).

Precision agriculture and sampling site selection

Another common application of *k*-means clustering is to create spatial zones across a study area for precision agriculture (PA) or soil sampling site selection.

In precision agriculture, *k*-means clustering is often used to identify similar areas within an agricultural field based on a number of characteristics. Common data sources include crop yield monitor data, soil apparent electrical conductivity (ECa), and elevation (Whelan et al., 2003). The clustering process enables subareas of fields to be managed separately by farmers to suit the particular characteristics of the zone (Gavioli et al., 2019). An example of clustering was its application to several seasons and years of digital

Fig. 4 Scores plot of the linear discriminant analysis (LDA) of the light fraction of soil organic matter under aspen, mixed, and conifer overstory. There is some separation between aspen and conifer along the first axis, with the first discriminant function achieving a percentage of separation of 92%. Light fraction under mixed overstory overlap with both aspen and conifer. The second discriminant function did not achieve a good discrimination, with only 7% separation.

yield maps to create different zones of potential crop yield, and then differing amounts of fertilizer were applied to match the potential yield in each zone.

The *k*-means clustering is also commonly used to decide where to take soil samples from across a study area. The process typically involves clustering a suite of existing data layers to create zones of similarity, and then applying a stratified random sampling approach to select sites. Fig. 4 shows a typical example of spatial clustering across several agricultural fields for The University of Sydney farm property L'lara in Australia from Filippi et al. (2019). In this example, digital soil maps, a digital elevation model, air-borne gamma radiometric data, and remotely sensed satellite imagery were used in the clustering process (refer to Table 1), with the optimal number of clusters determined by the elbow method. The proportion of the total study area that each cluster covered was then determined, and the number of samples to extract within each class was based on this. The overall number of sites to be sampled was pre-determined based on cost and practicality, as is typically done. In this case study, 30 sites were selected and the number per cluster was proportional to the cluster area. The sites were then selected randomly to determine the exact location of samples (Fig. 5).

An alternative

There are many algorithms available to group or cluster data points, and the choice of method depends on the dataset size, structure, and the goal of the analysis. However, *k*-means clustering is consistently reported to perform well and is fast, robust, can deal with large datasets, and is easily implemented (Cebeci and Yildiz, 2015; Román Dobarco et al., 2021b). These are key reasons why the algorithm has been so popular and continues to be to the present (Heil et al., 2019).

However, it is acknowledged that *k*-means clustering does not deal with scattered or overlapping clusters well, and fuzzy clustering approaches are better at accounting for this (Viscarra-Rossel and Webster, 2011). In fuzzy clustering, every data point belongs to every cluster to a certain degree of membership. Because of this, fuzzy clustering is more suited to more complex and high dimensional datasets, such as soil spectra (Viscarra-Rossel and Webster, 2011).

Conclusions

Advances in technology enable us to measure a multitude of attributes related to soil, many of which are difficult to interpret in their raw form. Given the array of possibilities, knowledge of multivariate techniques is an essential part of the soil scientist's toolkit to help their understanding of the state and function of soil. In this chapter we have presented one common approach for three classes of multivariate techniques, namely dimension reduction, supervised and unsupervised classification. Each is illustrated with an example to improve understanding. In addition, for each approach we described an alternative that soil scientists should consider

Fig. 5 The distribution of eight clusters derived from a *k*-means cluster analysis, and the locations of the soil sampling sites randomly selected within each cluster across The University of Sydney farm L'ara, NSW, Australia (Filippi et al., 2019).

because it could be more useful in some cases. This chapter is by no means comprehensive. Other fields such as computer science, data science and statistics are also developing new approaches so the reader should consider this chapter to be the start of a journey and keep their mind open to explore and test new approaches as they become available.

Abstract

Machine learning refers to a set of tools to establish models of linear or non-linear relations or other previously unknown relationships in complex data. In soil science it is widely used to create soil maps, to derive difficult to measure soil properties from sensor data or to provide information for soil related decision-making in agriculture. Machine learning algorithms based on decision trees are among the most popular techniques. Models with good predictive power are complex, but often outperform simpler models from classical statistics. Interpretation with algorithms that subsequently analyze the models is possible yet challenging.

Key points

- Machine learning encompasses a wide range of approaches that enlarge a soil scientist's statistical toolbox.
- Machine learning refers to methods to establish models of linear, non-linear, interaction type relations or other previously unknown relationships in complex data.
- Often a model with good prediction power is complex and difficult to interpret. Tools applied after the model building provide insight into the modeled relationships.
- Soil science applications mostly use supervised machine learning to predict unknown soil information when auxiliary information is available.
- Algorithms based on decision trees are among the most popular techniques.
- Machine learning is widely used to create soil maps, to derive difficult to measure soil properties from sensors data or to provide information for soil related decision-making in agriculture.

Introduction

Investigations of soil–environment relationships to understand and predict soil better have a long tradition in soil science. The quantitative analysis of these relationships is studied within the field of Pedometrics. Increasingly large datasets on soil itself or on environmental aspects describing soil are available. For instance, sensors that record soil moisture at frequent intervals or the spectral reflectance of a soil sample, aerial images with large numbers of spectral bands, elevation models showing detailed terrain features or harmonized databases assembled from various archives provide valuable information on soil. The analysis of such abundant data with classical statistical approaches, for example with a linear regression, has become increasingly challenging. The data embrace several types of data which are often correlated making it difficult to choose relevant variables for a certain goal.

Imagine that your aim is to generate a map of topsoil organic carbon for land management and climate mitigation. Your budget allows you to take and analyze only a limited number of samples from the study area. Therefore, you plan to use existing information of the study area, for example relating images of two satellites with four spectral bands each to your topsoil organic carbon measurements to support mapping. But how do you know which satellite you should use? Should you calculate vegetation indices from the bands? Which bands or indices are relevant variables to include in such a model? Should you exclude the bands that are correlated? Is the relationship linear or do you need to transform your bands by some function? If yes, which function?

To answer these questions, you decide to start fitting a linear regression model and to check each band by adding and removing them from your model. Then, you verify if your predictions according to a validation measure become better or worse. You retain a variable that improves the validation measure, otherwise you remove it. Because of the large number of combinations, it would take you a considerable amount of time, but eventually you would find a possible model to predict topsoil organic carbon for your study area. In this way, you let yourself be guided by the data to ‘learn’ a model structure by a stepwise algorithm where each step was decided by you.

Such a process can be tedious, time consuming and in the end, you cannot be sure if you stopped too early to search for the best model. Furthermore, if more samples become available you have to start again. To overcome numerous constraints while exploring statistical models soil scientists started to use machine learning. Machine learning refers to a set of algorithms that basically follow the same learning procedure, just in a more formalized and statistically sound way.

Unlike geostatistics, e.g. kriging approaches – which have been fostered by many soil scientists or statisticians working on soil mapping – machine learning tools have developed outside soil science. Several advances have led to successful adoption of machine learning. In addition to the large soil and environmental datasets available, progress in computer science and statistics, open source and easy applicable software and affordable computational power have made widespread use of large data and application of machine learning possible.

What is machine learning?

Machine learning refers to a set of tools to establish models of linear, non-linear, interaction type relations or other previously unknown relationships in complex data. It is an interdisciplinary field of computer science and statistics and is considered a subfield of artificial intelligence (AI). Depending on whether a computer scientist, a statistician or mathematician teaches machine learning the vocabulary and focus differ. Computer sciences define machine learning from an algorithmic position as the science of “how to program computers so they can learn from data” (Géron, 2017, p. 2). The often synonymously used term of statistical learning stresses the fact that machine learning methods are not just ad-hoc algorithms but have a sound statistical background (Hastie et al., 2009).

The boundary between classical statistics and machine learning is blurred. Classical statistics analyzes data to infer knowledge, for example by calculating p -values or searching for easily explained models and relationships. Often prior hypotheses about relationships are formulated and parametric methods are used, meaning that assumptions are made about the form of the relationship. The use of a predetermined form of the functions used in the model (e.g. linear relations between variables y and x) often assumes a specific distribution of the data analyzed (e.g. a normal distribution). An important part of the modeling therefore is to verify the assumptions of the model used to avoid a suboptimal model fit or incorrect conclusions. This can be done by analyzing the residuals that were not explained by the model (Gareth et al., 2017).

On the other hand, a machine learning method derives the relationships in the data by an algorithmic procedure, hence it is data driven. Machine learning focuses mostly on prediction, and it is only recently that their importance to gain knowledge, e.g. on soil processes has been stressed (Wadoux et al., 2021). Machine learning is often non-parametric. This means no prior exact form of the relationship is given and no assumption about the distribution of the data is implied. There are, however, also parametric machine learning methods where algorithms create models on base procedures that have a predefined functional form. Machine learning can handle high-dimensional data even if there are more explanatory variables than observations (many multivariate methods cannot do this). Correlated variables are dealt with so that they do not disturb the model fit and models are built with little to no user interaction.

Machine learning approaches can be classified into three main types. For soil scientists the most important type is supervised learning, whereas unsupervised learning is less widespread at present but has many meaningful applications in soil science. Reinforcement learning, another variant of machine learning, is rarely applied. It is a step-by-step improvement in learning that

is used, for example, in robotics where direct sensor feedback is processed to learn for future decisions. In crop production, it has been applied to sensors controlling irrigation (Sun et al., 2017). Here, I focus first on supervised learning then on unsupervised learning. For each type, popular methods are briefly explained.

Supervised learning

Assume that we observe a quantitative response variable Y and at the same n locations or on the same n soil samples (observations) we observe p potential predictor variables $X = X_1, X_2, X_3, \dots, X_p$. Suppose there is some relation between Y and X in the form of:

$$Y = f(X) + \varepsilon, \quad (1)$$

where f is an unknown function of X and ε is a random error term and represents the part, also called residual, that cannot be explained by $f(X)$. Supervised machine learning refers to a set of approaches to estimate f from the given pairs of Y and X (Gareth et al., 2017). The topsoil carbon measurements in the above example ‘supervise’ the building of the model, also termed model training. Topsoil carbon Y is then called the response variable or short response, as used in this chapter, or also dependent, output or target variable. The values X of the satellite image bands at the sampled locations are auxiliary information synonymously named independent, explanatory or input variables, covariates, features or predictors, the latter is used in this chapter. The whole set of X is often referred to as feature space. Like geographical space it can be imagined as a high-dimensional space that covers the thematic aspects of the observations.

The goal of model building is to find f that fits best to the data. A form for the function f needs to be defined and the optimal parameters of this function are estimated from the data. If Y is a continuous numeric response variable estimation of $\hat{f}$, it is a regression problem, if Y is categorical with two or more levels it is called a classification. Most machine learning approaches can include mixed data with X being continuous and categorical. A prediction task, also called forecasting if the goal is to predict about the future, aims to find $\hat{f}(X)$ that allows good predictions of $\hat{Y}$ to be computed for new locations or samples where just the predictors $\hat{X}$ are known. Estimated $\hat{f}(X)$ can be analyzed to gain insight into the relation of $\hat{Y}$ and X to improve model building or to learn about soil processes (Fig. 1).

Should we choose a simple or a complex model?

Some methods are more restrictive and less flexible regarding the shape that the function f can take while others allow f to be more flexible. For example, a linear regression is a relatively inflexible approach because it can produce only linear terms compared to smooth spline functions which can become highly non-linear. One could reasonably ask: Since soil processes and soil–environment relations are profoundly complex why should we ever choose a restrictive model with very little flexibility?

There are reasons why we should restrict flexibility, but to decide the optimal degree of restriction is challenging. If we are mainly interested in gaining knowledge about the relations between X and Y then a simpler model is more accessible to interpretation. More complicated shapes of f make it difficult to understand how individual predictors are related to the response variable. A model that is too simple might, however, lead to an oversimplification in the interpretation of the complex nature of soils.

If the aim is to predict, one often uses much more complex models to capture all possible relations in the data. Nevertheless, for prediction we have to restrict the model flexibility because the most flexible model will not create the best prediction. It will fit well to the training data, but with little ability to generalize beyond the current dataset and predict the response variable $\hat{Y}$ well for newly

Fig. 1 Schematic view of a supervised learning task for the generation and prediction of soil knowledge. The sketch shows a categorical response variable (e.g. soil structure class) and four numeric predictors (e.g. slope, clay content) that are used to train a non-linear model searched for by an algorithm. An optimal model is determined by calculating predictions for a test set not used to create the model and by comparing them to the observed values. Only if this assessment is satisfactory, may one use the model to gain insight or predict at locations or for soil samples where the target information is missing.

Fig. 2 Prediction error on training data (bright solid line) and new observations (dark solid line) in relation to model complexity illustrating the trade-off between model simplicity and prediction accuracy. In addition, the generalization error is decomposed into model bias and variance (dashed lines). The small bottom panels display a scatterplot of a response and predictor variable with three functions of different flexibility fitted to the data points demonstrating under- and over-fitting.

observed $\tilde{X}$. This situation is called overfitting. If a model is not flexible enough to map the basic structure in the data, then it is underfitting and its performance is weak on unseen data (Fig. 2).

The dotted lines in Fig. 2 show how the prediction error can be decomposed into model bias and model variance (Hastie et al., 2009). Variance refers to the degree by which f would change if we used a different dataset to estimate it. Large variance is observed if only small changes in the dataset, for instance by adding a few new soil samples, result in large changes in f . Bias, i.e. systematic distortion in the estimation of f , is introduced by approximating the usually very complex soil–environment relationships by a much simpler model. More flexible models generally result in less bias, but in an increase of variance. In a prediction setting, the challenge is to find a balance that allows enough model flexibility to capture the main structure to reproduce the general characteristics. At the same time the model needs to be restricted to avoid over-adaptation to the training data. Successful algorithmic procedures for prediction allow flexibility, but at the same time use strategies to reduce variance.

Strategies of machine learning algorithms

To find a balance between bias and variance, machine learning algorithms for supervised learning follow different strategies. The most often used approaches and associated methods are described in this section (Gareth et al., 2017; Géron, 2017; Hastie et al., 2009; Tutz, 2012).

Regularization

A stepwise forward selection for linear regression includes relevant predictors by testing them sequentially. Each predictor is tested and only the predictor that decreases the model error most is added. Adding of predictors is stopped when model improvement falls below a threshold. A linear model becomes more flexible the more predictors are included. In stepwise forward selection, and also in stepwise backward or best subset selection, model flexibility is controlled by using a subset only of all p predictors.

A more elaborate way to control the predictors in a linear model is regularization of model coefficients. Instead of a predictor being fully in or fully out of the model fit, it is used partially. All p predictors enter the model, but the regression coefficients are constrained. Instead of just minimizing the sum of squared errors an additional penalty is imposed on the size of coefficients. If the penalty increases, the coefficient estimates shrink toward zero. Some coefficients might even become zero which removes a predictor from the model. Ridge regression or lasso are the two best known techniques for regularization. They result in linear models where coefficients are estimated differently from ordinary least squares regression. Compared with the latter, ridge regression and lasso can even be applied when there are more predictors p than observations n .

Component-wise gradient boosting

Another way to control the inclusion of predictors and the size of coefficients is the gradient boosting algorithm. It selects predictors in a forward stagewise manner but compared to stepwise forward selection for linear regression it is not greedy, i.e. it develops the

model only slowly. It also uses an adaptive way to reduce model variance step by step. Instead of fitting the models to the response variable, at each iteration the model is fitted to the residuals of the previous iteration in choosing the best predictor to explain the remaining variance. The model is updated sequentially by adding the best performing predictor with a partial effect only, e.g. by shrinking it to 10% of its original size. Because of the small step size many iterations are needed. Each predictor can be added multiple times to ensure slow learning of its effect without overfitting the training data. The components tested in each boosting iteration are called 'base learners'. A base learner is a basic function and can take any form such as linear regression, a spline function or decision tree. The latter are the most popular base learners for boosting, the algorithm is known as 'gradient boosted trees.'

Decision trees

Tree-based methods split the predictor space into a set of rectangles by a procedure called binary recursive partitioning. The data are split into two portions by a predictor. Thresholds are tested to find the best split criterion for each predictor, and the predictor and its optimal threshold are chosen to produce the smallest error statistic calculated on the training data.

Each of the subsets is split further in two portions with the same or another predictor until a stopping criterion is met. Because the splitting rules to form this type of model can be summarized as tree diagrams, they are called decision tree methods. The most popular variant are classification and regression trees (CART). For continuous responses the squared sum of the residuals is minimized at each split, and for categorical responses the Gini index that measures the ratio of wrongly classified observations in the training data is often used. For each of the resulting final observation subsets (tree end nodes or tree leaves) decision trees use a simple model to compute the predictions. In CART the mean or the majority 'vote' of all observations inside each tree leaf is used. Other approaches like Cubist compute linear regressions at each end node.

Decision trees are easy to interpret and to apply and allow for non-parametric model estimation. Unfortunately, they often have poor prediction accuracy. Fully grown trees tend to overfit the data, so cropping (pruning) of the trees was introduced. Nevertheless, decision trees remain procedures with a large model variance, but low bias. The machine learning community introduced several strategies to overcome the drawback like combining many decision trees in component-wise boosting as introduced above.

Bagging

Another strategy to prevent procedures with large variance from overfitting is bootstrap aggregation or in short bagging. Bootstrapping is a widely applied and powerful statistical tool. In its non-parametric form, it repeatedly draws random samples from the training data. This so-called resampling creates numerous new training datasets that have identical statistical properties in terms of data distribution compared to the original training data. No parametric assumptions about the distribution of the data are required. Resampling imitates having multiple sampling campaigns in the same study. The model of interest is fitted to each of these samples and predictions are computed. The numerous models provide approximate error distributions or balance for high variance of models by aggregating the predictions, usually by their mean.

A popular method that applies bagging to decision trees is random forest (Fig. 3). It uses the bootstrap idea twice: on the observations Y and on the p predictors in X . Many trees are fitted to bootstrap samples of the original data. To ensure further that the trees are dissimilar, m of p predictors are randomly sampled at each split and only these are tested as split candidates. The trees to create random forests are fully grown and predictions are averages of all trees.

Fig. 3 Visualization of the bootstrap with two repetitions using decision trees as in random forest. $X_1, 2, 3$ are the predictors used to partition the data. $t_1, 2, \dots, n$ represent the individual thresholds optimized for each tree. For observation y_i the estimation of uncertainty with a quantile regression forest is illustrated. For each tree leaf (tree end node) the observations are kept. All the observations of leaves where y_i is found are pooled to obtain the full distribution. This predictive distribution allows to compute prediction intervals for new observations with the same values in $X_1, 2, 3$.

Support vector machines (SVMs)

Another method to approach complex datasets are models based on so called support vectors. They originated as a classification tool, and were then expanded for regression tasks also. The models are built by identifying characteristic observations within a dataset that are used to split the data into the classes of the response variable. These observations are used to define decision boundaries for the splits and are called support vectors. The shape of the decision boundaries to partition the data may be linear, but non-linear functions can also be used (e.g. radial kernel functions that result in smooth rounded boundaries).

Data can rarely be split perfectly along a decision boundary; therefore, a certain number of observations is allowed to be wrongly assigned. The decision boundaries are not crisp but are surrounded by a so-called soft margin that allows some observations to disregard the boundary. In addition to the shape of boundaries, the width of these soft margins is a further way to control model flexibility. Observations close to the decision boundaries only influence estimation of the model, hence support vector machines are not sensitive to outliers in the data. This property and the good control of model flexibility often results in good predictive performance.

Artificial neural networks (ANNs)

The development of artificial neural networks was inspired by the biological neurons in our brains. This analogy is not universally supported nowadays, however, these networks can be explained by artificial neurons that operate like switches or nodes as for neurons in the brain. Each neuron takes one or more binary inputs and has a binary output. A neuron becomes active if the rule to switch it on was fulfilled, for example at least one of the two previous neurons needs to be active. An artificial neural network consists of multiple so-called hidden layers of such neurons (computational steps) that transform model input into predictions. Neurons may also store numeric values in addition to an on-off switch, and the rules to transform the values from one layer to the next may be a complex function (activation function). Moreover, weights are applied to the values handed over from the previous to the next neuron. Simply, the goal of a neural network is to extract linear combinations of the predictors to obtain new predictors and then model the response variable as non-linear functions of these predictors.

The setup of hidden layers and structure of how rules update the neurons (function to activate neurons) is called the architecture. Neural network models take 'normal' data tables as input. But complete images may also be passed to specific implementations. Convolutional neural networks derive multiple layers of new features from the input images by applying different filters (augmenting step) before these transformations are used in a network as described above. This type of neural network is often referred to as deep learning.

Artificial neural networks perform especially well with complex prediction tasks and when a huge quantity of data is available. Model flexibility is balanced by layers that dropout and deactivate a predefined number of neurons in a layer. Furthermore, overfitting is controlled by a slow learning rate as in boosting (see above) applied to each learning iteration and by using only a randomly chosen subset to train the network and optimize weights.

Ensembles

Component-wise boosting and bagging described above combine many models of the same type to increase prediction accuracy, hence they already form model ensembles. To merge predictions from several models is not limited to using the same model type, for example in random forest. Model ensembles can be formed by producing new predictions from the predictions $\hat{y}$ of two or more models that follow a different approach. Such ensembles often outperform the predictions of a single machine learning approach because they capture different types of relations in the data.

There are several methods that merge multiple model predictions into one. A simple model is often used such as a simple or weighted mean of all predictions (model averaging). Overall prediction accuracy or local uncertainty can be considered to define weights. Predictions of well performing models receive larger weights, whereas those of poorly performing models have smaller weights. Another strategy is stacked generalization also called stacking, whereby a new model is trained using the predictions as explanatory variables. Constrained linear regressions are mainly used and optimal coefficients (= weights for each model) are chosen based on a new training dataset.

Model selection

So far, we have learned many approaches that might all seem feasible to apply to our data, but which should we choose? Unfortunately, there is no 'free lunch' in statistics. No method outperforms all others over all possible datasets. We do not know a priori which approach, which algorithm settings (tuning parameters) or which selection of predictors perform best on our data to achieve our goal (Hastie et al., 2009). Moreover, two models of completely different structure might perform equally well (model multiplicity, Breiman, 2001).

Soil scientists chose machine learning methods based on knowledge from previous studies that performed well on a similar task, or they test multiple approaches and select the best performing one. Predictors are not always selected. Many machine learning algorithms use all the predictors that are offered, some use just covariates that improve the model at a certain step, for example boosting or regularization where exclusion is part of the learning. Machine learning can handle many irrelevant predictors. With the strategies explained above the exclusion of covariates from the model is not necessary from a statistical learning point of view.

(Hastie et al., 2009). For ease of interpretation soil scientists often prefer a model with fewer covariates and processing becomes easier if only a subset is used to compute the model predictions.

One possibility is to pre-screen the set of potential predictors prior to applying machine learning. The predictors are compared to the response variable one by one and only if they pass a certain criterion, i.e. the significance level of a statistical test, are they used in the subsequent machine learning algorithm (univariate filtering). For correlated predictors only one is retained based on a similarity criterion like a correlation coefficient or the variance inflation factor (VIF). An approach using the machine learning model itself is called recursive backward elimination. To achieve a smaller set of explanatory variables, the importance of each variable in the machine learning model fit is evaluated. The least important variable is then excluded, and the model is fitted again. This procedure is repeated until an optimal number of variables based on the best performing model is obtained. A similar approach is the Boruta algorithm. It adds so-called shadow predictors to the model that were permuted randomly. Only predictors more important than the randomly shuffled predictors are retained in the model.

In addition to the selection of relevant predictors, machine learning algorithms have tuning parameters that can be optimized with the current dataset. They are settings that control the number of iterations, such as the number of covariates tested at each step in a random forest, the degree of shrinkage of coefficients in lasso or the smoothness of a kernel function in support vector machines. A grid search is usually applied to find optimal values for the tuning parameters. A grid or matrix with tuning parameters at different intervals is defined and the machine learning algorithm is applied for each parameter combination. The best performing combination for a dataset is chosen to compute the final model.

Model assessment and uncertainty

It is now time to discuss how 'best performing' or 'optimal' parameters are evaluated, how the 'best' model is chosen and what we mean by 'good' predictions. Model assessments have two goals:

1. to estimate the performance of various models and choose the best one by evaluating its 'goodness-of-fit' to the data or its capacity to generalize beyond the training dataset,
2. with a final model, estimate its prediction or generalization error if applied to new data not seen by the model before.

If our goal is to predict $\hat{Y}$ on new observations $\tilde{X}$ the best model $\hat{f}(X)$ has the smallest generalization error. This requires application of the model to new observations. To select the best model the data are often split, and the different models are trained on a subset only. Predictions are calculated on the remaining data and the prediction error is evaluated. If this process is done repeatedly, it is called cross-validation. The data are split in, for example, 10 equally sized subsets and each time one of the 10 sets is removed from model training.

The final model is evaluated ideally by a new and independent dataset. These data are often called test data, and the process independent or external validation. Additional soil sampling is often not feasible; therefore, data splitting is used by assigning roughly 20% of the soil samples to a test data set that is not used in the model selection process.

By computing predictions $\hat{Y}$ for the test data set we obtain a set of pairs of observations and predictions. From these we can calculate differences and descriptive statistics. In regression problems prediction error is often calculated as the root of the squared differences between observations and predictions (root mean squared error, RMSE). If we choose to predict classes, the prediction error can be calculated as the percentage of wrongly classified individuals (error rate). Both represent an overall error. There are many possible criteria (Wilks, 2011) and depending on the goal we might want to optimize something more specific. For example, in a task to map sites with soil pollution we would like to identify all the polluted locations, therefore, we might prefer to avoid false negative predictions and optimize on the 'hit rate,' i.e. the percent of correctly identified polluted sites.

Assessment of model accuracy results in overall estimates of mean prediction error for a map or pedotransfer function, for example. In addition, it is important to quantify how uncertain our predictions of $\hat{Y}$ are at new observation sites compared with sampled sites. Uncertainty originates from the estimation of $\hat{f}(X)$, because it is only an approximation of the true underlying process that produced the data. Moreover, $\hat{f}(X)$ does not account for all the variance in Y , described by in ε in Eq. (1).

Parametric models such as ordinary least squares regression assume distributions for f and ε and enable direct quantification of the dispersion of the two quantities. Most machine learning methods lack assumptions about the statistical distribution of model parameter and errors. One solution is to simulate the combined distribution of $\hat{f}$ and $\hat{\varepsilon}$ by a resampling tool, i.e. bootstrapping. Fig. 3 illustrates this process for decision trees which results in one combined distribution for uncertainty in estimating $\hat{f}$ and $\hat{\varepsilon}$. Another versatile approach to quantify prediction uncertainties empirically is based on partitioning of the feature space. Clustering (see below) is used to divide the predictor space, and accompanying local uncertainties are assigned to the predictions belonging to the same cluster (Malone et al., 2017).

Model interpretation

Unfortunately, accuracy of prediction and model simplicity with ease of interpretation are incompatible. Most machine learning models with good predictive power are highly complex; they establish response–predictor relationships non-linearly in various layers or with a multitude of single models. In a simple linear regression, the estimated coefficient β can be interpreted directly as the increase in the response variable $\hat{y}$ by the amount β if we increase the predictor by one unit. The many model parameter estimates

Fig. 4 Relative importance of five variables to predict soil bulk density sampled in forest soils of Switzerland by a random forest model (A). The partial dependence plots for the two most important predictors reveal non-linear effects (continuous predictor [B] and a categorical predictor [C]; based on data from Nussbaum et al., 2016).

resulting from machine learning have no such simple interpretation nor the optimized tuning parameters. On first sight, machine learning appears to be a black box. Post-processing tools applied after model training provide insight to move toward the understanding of modeled relations. Independent of the machine learning algorithm, importance of the variable and partial dependence plots can be applied.

Model-agnostic relative variable importance can be obtained by randomly permuting the predictor of interest. The model structure and all other predictors are kept fixed. Predictions are then re-computed with one predictor shuffled and the decrease in prediction accuracy is evaluated. The larger the decrease, the more important is this predictor relative to the others (Fig. 4).

After the most important predictors have been identified a graphical display of the partial or average dependence helps us to understand their approximate effects. To compute the partial dependence $\hat{f}(X_s)$ of a predictor s on the fitted values of a response $\hat{y}$ values from all other predictors are averaged. Such displays, however, have a more complex interpretation if there are strong interactions or correlations between the predictors.

Unsupervised learning

Unsupervised learning is a technique where the structure of X with p variables at n observed locations or samples is modeled without having a response variable Y . Unsupervised learning is often used for exploratory purposes to learn about the data, but it also supports sampling designs (Brus, 2019) or uncertainty mapping. Two popular sets of approaches are clustering and tools to reduce the dimensions of X .

Let us look at an example: Imagine you received a small project extension to measure aggregate stability on 10 of your 50 samples on which you had already measured carbon. You create 10 piles of the sample bags with similar soils based on their visual properties like soil color, soil structure or gravel content and size. Then you take one sample per pile that seems typical for this group. The search for a subsample that represents our soil samples well is an unsupervised problem because we do not yet know the aggregate stability. With many samples or more properties to evaluate this manual process becomes confusing. However, the choice of samples could be done by statistical clustering resulting in a reproducible and less subjective choice of samples.

Clustering

Clustering is a broad set of techniques to find subgroups in the data. Observations are assigned to groups, i.e. clusters, so that a cluster encompass similar observations while being quite dissimilar to the observations in other groups. Similarity is quantified by relative distances to the content of a set of chosen variables.

Clustering approaches differ mainly in how the distances between the observations are calculated and how the clusters are formed. Fuzzy clustering methods allow observations to become a member of several of the subgroups formed. Hierarchical algorithms either start with the full data set and iteratively split it into smaller groups (divisive) or start by combining similar observations and continue merging them to larger groups (agglomerative). The hierarchical structure can be visualized by a tree-like diagram or dendrogram which helps to find an optimal number of clusters.

The k -means clustering approaches need the number of clusters to be pre-specified. The center of each cluster is then searched for by moving them toward the optimal location during several iterations. To choose the samples in the above example, a k -means clustering with $k=10$ could be used. The approach is known as feature space coverage sampling design because it spreads the samples over the multivariate distribution of the p variables used.

Dimension reduction

Clustering seeks to find homogeneous subgroups among the observations based on selected variables p , whereas dimension reduction approaches aim to find a low-dimensional representation of p that explains a large fraction of the variance in the data. Principal components analysis (PCA) is often used for this purpose. With p variables there is a p -dimensional feature space, but not all dimensions are equally interesting. There is often redundancy in the p variables because many might be correlated. The axes of the p -dimensional feature space are transformed by linear combinations of p so that the common variance of the variables is best represented. The new axes (directions), i.e. principal components are chosen to be orthogonal to each other and to embrace as much variance in the data as possible. The first few principal components explain the most variance in descending order and provide insight about the most important variables.

The principal components (PCs) can be interpreted by the contribution (eigenvector values) made by each variable to the component and the correlation structure of p can be visualized by plotting the eigenvectors in the plane of pairs of the leading PCs. Moreover, principal components can be used to build supervised models. For example, partial least squares regression (PLSR) is an approach that produces principal components in a supervised way to use as linear predictors.

Feature engineering and data fusion

So far, we have learned about methods that can handle large numbers of predictors X to build a model $f(X)$ to predict or explain a response variable Y or learn about the (complex) structure of X . Imagine a small study area where topsoil was sampled, and clay content measured. In addition, a digital elevation model is available for the area. Now we read in the elevation at the sampled location and relate elevation with clay content using one of the numerous tools described in the supervised learning section. With just elevation to explain topsoil clay would give us a very narrow picture of the soil forming processes. Digital elevation models (DEM), however, are straightforward to process and terrain derivatives such as slope, aspect, curvature, or the position in the landscape can be generated from these. Since we are expanding our predictors or features, this is sometimes called feature engineering. This preparatory task allows us to attribute contextual information to the topsoil clay samples, i.e. if a sample was taken at the valley bottom, in a small local depression or on a hilltop. However, none of the approaches mentioned above includes such information. In convolutional neural networks a local extract from a DEM around the sampling location can be included in the model and then processed in the augmenting step.

Preprocessing and the expansion of predictors is a standard procedure, however, for spatial analysis the scale(s) of the soil forming processes are generally not known beforehand. Machine learning approaches can deal with many correlated predictors, and derivatives of elevation models are often computed at multiple scales (e.g. 30-, 100- and 250-m pixel resolution). Model selection helps to identify the relevant scale for a certain response variable (Behrens et al., 2018; Nussbaum et al., 2018). Knowledge about soil forming processes, for example by consulting local surveyors, might form a further basis to derive additional informed predictors.

In addition to elevation data, remote sensing images from satellites or drones or signals from ground sensors are preprocessed in similar and sometimes more complex ways. In remote and proximal sensing literature this is often referred to as image or data fusion. Data fusion stresses the fact that several data sources are combined to improve efficiency to reach the goal (Grunwald et al., 2015). To combine satellite images, pixel-based approaches are widespread where single bands are combined into vegetation or soil reflectance indices, or characteristics over an image time-series are derived, e.g. maximum of a spectral index over the vegetation period (Demattê et al., 2018). Feature-based fusion approaches process each image separately, for example by unsupervised learning, and then combine the results. In addition, image fusion encompasses processing steps to combine different spectral and spatial resolutions. For example, a colored satellite image with low resolution might be improved i.e. sharpened by a greyscale image at a finer resolution (Chang and Bai, 2018).

Data fusion is not limited to imagery, i.e. spatial data covering a surface, but is often applied to ground sensor data measured at single points. No single sensor can approximate soils optimally. Sensor fusion integrates several signals, for example from spectral measurements done at different bandwidths that are optimal to approximate soil organic carbon, others for clay minerals. Proximal measurements may also be fused with wet chemical laboratory measurements into combined datasets for subsequent statistical analysis.

Processing of large data

In connection with machine learning the 'buzzword' Big Data is often used. Big Data in its narrower definition encompasses massive, unstructured datasets that cannot be stored and analyzed in traditional ways and that are often collected and processed in real time (Sagioglu and Sinanc, 2013). One dataset alone is often larger than the disk space of a personal laptop.

Large file sizes originate either from having many variables, many observations or both. In soil science very large datasets originate from genomic analysis, computer tomography on soil samples, various sensor data collected in precision agriculture or from global satellite imagery time series, abundant drone imagery and digital elevation models at high resolution. Although file sizes are large, and processing becomes challenging the data are structured and their size is not the magnitude of Big Data.

Nevertheless, the processing of large datasets is demanding and has only become widespread with the massive increase in computational resources (Rossiter, 2018).

It is possible to train machine learning models on small datasets using only the computing power of a personal laptop. One random forest fit with 1000 observations and 200 predictors, for example, takes a few seconds to complete allowing for multiple runs to optimize the tuning parameters. Models fitted to datasets with many observations, feature engineering, especially on spatial data and computing predictions for large study areas becomes more time consuming and require high performance computing (HPC) facilities. Companies offer such computing infrastructure of various magnitudes and set-up plans to rent for a restricted amount of time, known as cloud computing.

Computations on high performance computers are run in parallel. This means that a job can be broken down into smaller pieces and then the sub-jobs are passed to more than one computer node to evaluate them at the same time (Malone et al., 2017). Parallel computing is now implemented directly in many software packages. If not yet the case, the data soil scientist will have to employ a small extra implementation effort because he or she will have to evaluate which computations are independent and send them to separate nodes. Independent tasks are, for example, model runs with different tuning parameters or when a digital elevation model is cut into subsections and each section is processed separately. Assembling results from parallel runs or balancing of border effects between the subsections then become additional tasks in the workflow. Apart from the increase in computation time, the demand on computer memory becomes challenging. Either software needs to be used that includes memory save implementations by reading only the data currently needed from the disk or the data needing to be split and processed one piece at a time.

Data preparation and the application of machine learning algorithms is often done with programming languages such as R or Python (Géron, 2017; Malone et al., 2017). Both have many add-on packages that provide easy-to-use high-level functions of the newest implementations of tools to process large datasets and apply machine learning. Basic skills in writing code are required to call on computational tasks and to access high performance computing in the sense of giving orders one by one. No advanced skills in object-oriented programming or software engineering are needed nowadays.

Typical applications

In soil science there are numerous applications for the approaches described in this chapter. They can roughly be categorized into applications in space or space-time, at the level of soil samples or sensor data to support soil related decisions.

Spatial and spatio-temporal machine learning

Digital soil mapping exploits the relationship between observed soil information at the level of a soil pedon (point observation, e.g. soil profile or sample) and soil forming factors such as relief, climate, or geology. The latter are represented by spatial data available for the whole target area and enable predictions at unsampled locations and hence provide spatially continuous spatial information (Malone et al., 2017).

Response variables are basic numerical soil properties like subsoil organic carbon content, topsoil moisture or rates of soil erosion, categories such as soil types or ordered categories like drainage classes. Many predictors (20–300) are often prepared and included in models. Predictors are derived from elevation models, remote sensing imagery, geological maps, or existing legacy soil maps. If soil information from multiple sampling times is available, the data can be related to corresponding satellite images to allow a temporal component to be included in the model. Tree-based machine learning approaches like Cubist or random forest are among the most successful models used (Wadoux et al., 2020). The resulting maps display the most likely class or value of the modeled response variable. Moreover, uncertainty maps are provided showing the standard deviation or a 90%-interval of each prediction, for example.

There are many variants of digital soil mapping (DSM) adapting workflow to the current data availability in an area. Sometimes responses are derived from legacy soil maps at coarse scales. Such an approach, termed map disaggregation allows us to increase map resolution with more accurate predictors (Malone et al., 2017). Moreover, the validation strategy to estimate the generalization error of the maps depends on the individual situation regarding previous work to build on, budget and knowledge of staff in a mapping project. A fully independent dataset cannot always be sampled and validation by (repeated) data splitting can be done.

Transfer functions at the level of soil samples

Many soil laboratory measurements involve time-consuming sampling and costly analytical procedures, but they provide valuable information. It is a long tradition in soil science to approximate measurements by rules based on expert knowledge. If such rules are formalized to allow direct calculations, they are called pedotransfer functions. For example, soil bulk density is correlated with soil organic carbon which can be used as a proxy to predict bulk density for samples where organic carbon only was measured (Fig. 4). Furthermore, the use of correlated but less expensive field or laboratory measurements with spectral sensors, for example measuring visible to near or mid-infrared reflectance, enables many soil properties to be approximated accurately.

For (spectral) pedotransfer functions, models are trained at the level of soil samples and predictions are then calculated for samples where only the proxy measurement was done. Ordinary linear regression is a popular approach for pedotransfer functions with one or few correlated ancillary measurements as predictors. Spectral instruments often produce many correlated reflectance bands that are available as predictors. Dimension-reduction approaches like partial least squares regression or machine learning that

handles many correlated predictors such as random forest are often used to predict soil properties from spectral data. From large collections of potential spectral training data (spectral library) usually a sub-sample only is used for model training. The library sub-sample is selected to be similar to the samples to be predicted in terms of feature space.

Integration of sensors in soil related decision making

A major field of application for machine learning approaches is agriculture. Efficient methods for in-field soil property determinations are used to infer appropriate inputs to optimize crop performance and minimize environmental effects (Sharma et al., 2020). Precision agriculture relies on spatio-temporal mapping and transfer functions as mentioned above. Various types of sensors are used that scan vegetation or soil surfaces of complete fields and the data can be combined by sensor fusion. For example, sensors mounted on fertilizer or pest control machinery determine local nutrient deficiencies or diseases by classifying plant images by neural network algorithms. Machine learning based computer vision is further used for weed detection and elimination by farm robots. Arable fields are split into zones with similar soil properties by unsupervised machine learning by, for example, electro-magnetic conductivity or a bare soil drone image. Farmers use such management zones to adapt sowing width and fertilizer quantities or to develop water saving irrigation plans, together with their agricultural knowledge of their land.

Summary and future requirements

Machine learning is not a new technology. The first description of an architecture for an artificial neural network dates to 1943, classification and regression trees have existed since 1984 and aggregating models with bootstrap resampling technique was published in 1993 (Géron, 2020; Hastie et al., 2009). In soil science, only within roughly the last 10 years have complex machine learning procedures become widespread and approaches established. Emergence of easy-to-use open-source software, advances in computational power, increasingly freely available environmental data, newly assembled large soil data bases have all contributed to the increase in machine learning applications. Machine learning is not replacing classical statistics, but rather expanding the statistical toolbox of soil scientists. The task at hand and the available soil and predictor data decide the optimal choice of approach, which might be machine learning, classical statistics, or no statistics at all.

Currently, the following challenges regarding machine learning and soil science are being researched (Wadoux et al., 2021):

- How can soil knowledge be derived from the complexity of machine learning models? For each dataset there is likely to be more than one model (approach, set of predictors, selected parameter configuration) that predicts a response variable similarly well. The so-called model multiplicity needs to be considered for model interpretation, i.e. a not included predictor might be relevant if another predictor were to be dropped.
- How can available soil knowledge be introduced explicitly into the modeling process? Models learn from the data but cannot know about restrictions or combinations of values that clearly follow from soil processes.
- Models are often built independently for each response variable in a study area, for example if topsoil and subsoil carbon are to be predicted. However, responses are often related, and better predictions could possibly be achieved by including two or more responses in multivariate models.

Abstract

The concept of spatial scale is of fundamental importance in the analysis of spatial data. Issues such as scaling, multi-scale, data fusion, and change of support when analyzing spatial data are currently not given due attention. There is no unique or only one approach to deal with scaling or change of scale. Geostatistics offers several tools to deal with these problems, such as the regularization technique that evaluates the effect of scaling by operating on spatial functions, such as the covariance and variogram, rather than on data. In this chapter, a case study is presented to illustrate how geostatistics can deal with the issue of spatial scale.

Key points

- Scaling is related to the transfer of information across spatial scales
- In multi-scaling, the scales at which the analysis should be conducted have to be identified.
- Scaling may involve a change of support when the variable is estimated on a different volume than that of measurement.
- Geostatistics allows the multi-scaling and change-of-support problems to be addressed with variogram regularization and block (co)kriging.
- Geostatistical data fusion is an effective way to combine heterogeneous spatial data that takes into account change of support.

Introduction

Nowadays, we are inundated with an ever-increasing amount of data distributed in both space and time, i.e. the variables and parameters that describe the dynamics of a physical process in an environmental system. Several disciplines tackle environmental problems, therefore, this information has a wider range of applications, even with neighboring sciences such as economics and epidemiology. Advances in spatial information technology (SIT), such as the global positioning system (GPS), remote and proximal sensing, and geographic information systems (GIS), have contributed to the proliferation of spatial data and related Information Technology (IT) products.

There are several undoubted potential benefits of SIT, but it is important to shed more light on some theoretical and practical problems that can affect the various applications of spatial IT. Most of them include the issues of scale, geographical representation, spatial data acquisition and integration, and uncertainty assessment. In particular, the concept of scale is of fundamental importance in environmental investigations as it involves various aspects of spatial analysis. Although different definitions of scale exist, an effective framework considers scale, as a dimension that schematically comprises the triplet of 'support', 'spacing', and

'extent.' This view was mostly conceived in hydrology but is now accepted in almost all environmental disciplines (Blöschl and Sivapalan, 1995; Loague and Corvin, 2007). One of the advantages of the 'scale triplet' concept is that it can be profitably used for either monitoring activities or computer simulations, and can be applied in either the spatial or the temporal context (McBratney, 1998; Romano, 2014). An additional advantage of applying the triplet scheme to the spatio-temporal analysis of environmental variables and parameters is that a mismatch among the components of 'scale' can be highlighted more easily. A mismatch in scale in environmental studies often occurs between the measured and modeled attributes, and between the spatial scale of observations and that of simulated scenarios of a process that are provided to an end-user (i.e. what we wish to obtain) (see, for example, Teuling et al., 2006; Gentine et al., 2012; Nimmo et al., 2021).

Research indicates that the scale of a spatial analysis should match, as closely as possible, that of the process dynamics under study (Legendre et al., 2002; Wu and Li, 2009). However, a given process can manifest itself and evolve across multiple spatial scales, with complex scale dependencies of the relevant spatial patterns. Non-linear interactions between scales may also occur (Stahl and Hisdal, 2004; Nimmo et al., 2021).

The above concerns contribute to the need to introduce scale, in particular change in scale, in spatial data modeling, and the search for scale dependence and scale invariance (Sposito, 1998).

Aims and research significance

The purpose of this chapter is mainly twofold: (i) to address the concept of scale when analyzing geospatial data to extract spatial information and relevant patterns, and (ii) to discuss the problems of change of support and multiscale spatial modeling with complex and integrated environmental datasets obtained from different types of sensing systems. This chapter draws the reader's attention to two critical questions that could be overlooked when designing a sampling scheme or mapping spatial variables, especially when covariates are used.

The first question refers to up- or down-scaling (also referred to as aggregating or disaggregating) the available observations, i.e. the use of an adequate change-of-support model (Malone et al., 2013). The second question concerns the fact that spatial (but also temporal) processes evolve over different scales and show various levels of complexity (Kavvas, 1999). Variography is a robust tool to investigate the changes in spatial variance over different scales.

The few theoretical issues underpinning this chapter are primarily based on our experiences with the use of geostatistical tools. An illustrative case study serves as a practical example of how those concepts can be approached.

Scale, scaling, and the change of support

Theoretically, scale (a spatial scale, in particular) refers to a characteristic length of the problem at hand and is related to the concept of spatial dependence, which is an intrinsic property of many environmental processes and their spatial representations. Spatial dependence refers to the property of neighboring observations being similar and influencing each other (Tobler's law, 1970). Consequently, neighboring observations cannot be considered distributed independently and randomly, but rather are characterized by various degrees of spatial association. It is the existence of spatial dependence that underpins spatial interpolation that, in turn, makes scaling issues come into play (Grayson and Blöschl, 2000).

Scaling refers to the transfer of information across scales. In this chapter, scaling is considered to be the change in scale from the observations to the predictions and is required whenever estimates are needed at a scale different from that at which the data were collected or when spatial processes occur over a broad spectrum of scales that can show nested or hierarchical structures (Wu and Li, 2009). In multi-scaling, the scales and a set of scaling thresholds should be identified to determine at which scale(s) the analysis should be conducted. Scale sensitivity analysis and robust scaling methods help make this choice and develop spatial models that enable scale effects to be compensated for (Behrens et al., 2019). There is evidence from recent investigations that the use of multiple scales, when modeling an environmental process, has the potential to enhance the accuracy and precision of estimates (Behrens et al., 2019; Biswas et al., 2013a). There are cases, however, where it is unnecessary to take all scales into account and it suffices to concentrate on the dominant process and the associated scale (Behrens et al., 2019). In practice, the choice of a scale is usually influenced by an already pre-selected scale in the system under study and the objectives of the investigation (De Boer, 1992). A few scales only are likely to be important, nevertheless those that are less influential should not be completely neglected. It is crucial to understand which dominant process governs a given phenomenon, and if the spatial models corresponding to the various scales are sufficiently different to be considered independent (Phillips, 1988). The problem of identifying the optimal measurement scale for an investigation to be carried out remains.

Even though scaling involves changes in all three components of the previously mentioned triplet (Malone et al., 2013), in this chapter we will focus on the change of support. Spatial data are often acquired by sampling the area of interest at several positions and monitoring several state variables. In some cases, the measurement locations can be considered point-like (e.g. the rainfall amount measured by a rain gage or soil moisture measured by a probe embedded to a certain soil depth), whereas other sampling activities refer to units with finite geometric dimensions larger than a point (e.g. sample plots in a forest inventory or pixels in remote-sensing images). Finite-sized supports are common in environmental analyses based on areal units, such as forest stands or

agricultural plots. When spatial data are aggregated, the support of a variable is changed and a transformed variable is generated, which is related to the previous one but has different statistical and spatial characteristics (Castrignanò and Buttafuoco, 2020). The change of support is a key topic in quantifying scale effects and will be discussed in more detail in the section on geostatistics.

Spatial models of scale

In recent years, SIT has steadily progressed to become a more cross-cutting discipline which results not only in the production of huge spatial data sets but also in a variety of acquisition tools. An unprecedented amount of Earth surface data is currently provided not only from satellites and unmanned aerial systems (UASs) but also from critical zone observatories (CZO) and open-air laboratories. Moreover, these datasets are now available at a relatively fine spatial resolution, even at submetric scales with UASs, which can be used as auxiliary variables to enhance the information contents of sparse ground-based data (Qu et al., 2022).

Therefore, there is a need to define a set of techniques capable of analyzing a huge amount of multi-source data with different spatio-temporal and statistical characteristics. These techniques should take into account scale dependencies and the diversity of data sources, and be able to manage them efficiently and effectively to extract the maximum possible information. In other words, a coherent and efficient system of techniques is required for fusing large quantities of geospatial data. The scale, or scales, in a dataset should first be assessed and then the processes that produced those data should be modeled. After that, the spatial model should adapt the scale of estimation to that of the data. The many techniques available for this purpose include fractals, geographical variance, local variance, wavelets, and spatial statistics. For a given investigation these techniques should make it possible to identify the appropriate scales of measurement, extract information, and perform a variety of spatial procedures on the data. All the above-mentioned techniques assume that the scale associated with the largest variance represents that at which most processes operate (Wu and Li, 2009). Fourier and spectral analyses as descriptors of scale have been widely used in topography and landscape analysis (Perron et al., 2008). Unlike Fourier analysis, the wavelet transform method (Biswas et al., 2013b) uses a wavelet function that can be adapted to the appropriate scale for a given data set. For example, to determine the most appropriate scale at which pedotransfer functions (PTFs) can estimate spatially-variable soil hydraulic properties, Pringle et al. (2007) used the wavelet technique to explore how the variances and correlations of both observed and estimated variables varied with the spatial scale. These authors showed that when a simplified method is used to estimate a certain variable, it is likely that the estimates are scale-dependent. A simplified method can mimic the actual spatial variation of the target variable when working at a relatively large scale (i.e. when the spatial fluctuations are small), whereas this capability becomes weak when considering the spatial variation at a relatively small scale (i.e. when the spatial fluctuations become rapid).

There are different ways to assess the similarity between neighboring observations, including spatial autocorrelation (Cliff and Ord, 1973). Before using traditional statistics, one has to check whether or not the available data are uncorrelated. In the case of spatial correlation, the covariance or correlation coefficient between two variables are no longer expressed by a number but by a mathematical function of the distance between pairs of observations such as the variogram and covariogram in geostatistics (Webster and Oliver, 2007).

Geostatistics as a coherent framework for scale modeling and scale change

Spatial dependence is an intrinsic feature of many spatial properties. The Earth's surface is characterized by varying degrees of spatial variability, such that no portion of it can be taken as representative of the whole. Spatial dependence and spatial heterogeneity are two sides of the same coin that interact with each other. A coherent and efficient system of spatial analysis is required to (1) quantify the scales of variation, (2) decompose the total spatial variation into the component attributable to the measurement and the process-specific component to determine the corresponding scales; (3) evaluate the differences in spatial variability at different scales, and (4) characterize the impact of information transfer across multiple scales. This section illustrates how geostatistics can respond to the above questions.

In geostatistics, scale specifically associated with the measurement process is called 'spatial support.' It is worth emphasizing that support should not be confused with resolution (Malone et al., 2013). The latter term is used in sparse sampling to address the average sampling distance and, in the case of raster data, is the size of the grid mesh or pixel. Here, the measurement scale will refer only to the support. Both support and resolution (depending on the density and arrangement of samples) affect estimation and the estimation variance. However, in this chapter, the focus is on support and not on sampling.

In many applications of spatial data analysis, the input dataset comprises measurements done on point supports, whereas in others they are carried out over a finite area or volume. Here, we will discuss the problem of how the spatial variation of an attribute relates to that of the same attribute when it is estimated on a different support (change-of-support problem). It is fundamental to understand how the spatial support relates to the scales of natural spatial variation, which are detectable through such a measurement but which also depend on the particular sampling pattern adopted. It is a complex subject. In this chapter, we restrict our analyses to how the sample support may affect the determination of intrinsic spatial variation. In practice, the values of properties are obtained from measurements on a given support, which represents a finite element of the space of a given size,

Fig. 1 View of reality through the sampling screen. Modified from Atkinson PM, Tate NJ (2000) Spatial scale problems and geostatistical solutions: A review. *The Professional Geographer* 52(4): 607–623.

geometry, and orientation. Assuming a continuous random field (Webster and Oliver, 2007), an observation $z_v(\mathbf{x}_0)$ can be considered a realization of a random variable (RV), $Z_v(\mathbf{x}_0)$, which is the spatial average or integral of Z over a finite support v centered on the point $\mathbf{x}_0$. Formally, it can be expressed as follows:

$$Z_v(\mathbf{x}_0) = \frac{1}{v} \int_{v(\mathbf{x}_0)} Z(\mathbf{y}) d\mathbf{y}, \quad (1)$$

where $Z(\mathbf{y})$ is the property Z defined on a point support. The spatial variation of Z is then averaged over the given support to produce a single mean value. It is important to distinguish between two fundamental but different scales: the scale or scales of measurement and the scale or scales of spatial variation that can be identified from the measurements.

Unfortunately, these two types of scales do not always coincide because ‘reality’ can only be observed through the implementation of a measurement system, consisting of the particular equipment used and the sampling pattern (number, locations, and support of samples), that produces spatial data that can subsequently be analyzed (Atkinson and Tate, 2000). This leads to two important considerations (Atkinson and Tate, 2000): we cannot observe ‘reality’ directly but only through the sampling screen (Fig. 1), so what we observe is not the reality (unknown) but always a filtered version of it.

Further, the scales of spatial variation can only be obtained from the analysis of data sampled at the given spatial scale(s) of measurement. The latter highlights how the scales of spatial variation obtained from the analysis of the data are intrinsically linked to the measurement scales of the sampling framework in which those data were collected. In the following, we will only assess the influence of support on spatial variation using geostatistical tools.

Multi-scaling

For a description of spatial variation with geostatistics, the interested reader is referred to manuals such as Goovaerts (1997), Wackernagel (2003), and Webster and Oliver (2007). Here, we will deal only briefly with those concepts most closely related to support. The dispersion variance $D^2(v, V)$ represents the variation of all data on a support v within a domain V , while the covariance function $C(\mathbf{h})$ represents the variation between pairs of data on support v [v, v_h] whose locations in the sampling frame are separated by the distance vector $\mathbf{h}$, called the lag.

Behrens et al. (2019) presented a method to define the effective scale interval with defined lower and upper scale limits for spatial modeling. They used the range of the variogram of a soil property of interest to determine the upper limit of the relevant range of scales, and the product of the nugget/sill ratio by the range to approximate the lower limit of the scales. Fig. 2 illustrates this with an example of how, according to the authors, the possible range of variation of scales can be determined. This lower limit is based on the assumption that the spatially uncorrelated variation of the soil property, represented by the nugget effect can be converted to the spatial variation at a given scale if the nugget is relatively large, which mainly results from too coarse a sampling scheme.

Furthermore, an experimental variogram may embrace more than one spatial scale and a nested model should be fitted that comprises a combination of multiple authorized models, each with its range representing a given scale of spatial variation (Webster and Oliver, 2007). An important consequence of the above is that the variogram can be used as a useful exploratory spatial tool to determine if multiple scales of spatial variation are present in a set of data (Fig. 3). Fig. 3 shows the nugget variance (A), the short-scale variation (B), the longer-scale variation (C), and the combination of the three components (D).

Fig. 2 An example to illustrate the way to obtain the relevant range of scales using a variogram model according to Behrens et al. (2019): the lower limit (a_1) and the upper limit (a_2) of the relevant range of scales.

Fig. 3 Composition of a nested variogram.

Change of support

In this section, we consider in more detail how the change of support affects the scales of spatial variation that are observed. It is common in remote sensing, for example, to compare point on-the-ground measurements of a variable, i.e. measured on supports that are small compared to the pixel size of data from a raster image whose support is the pixel. If the aim is to model the relationship between the two variables, e.g. through regression or techniques in machine learning (Jin et al., 2021), and then use the relation to predict the point variable at unsampled locations, the accuracy of the prediction is expected to be quite small. The relationships between the variables are strongly scale-dependent (King, 1991), therefore such a strategy is not recommended. A proper procedure would involve rescaling or upscaling the point measurements (i.e. the small scale at which the variables are observed) to the pixel scale (i.e. the larger scale where a model applies) before a comparison is made with the raster variable. To obtain mean values of the point variable at the pixel scale, one or more samples per pixel should be available, which is rarely the case. One way of solving the problem could be to use interpolation by punctual kriging (Goovaerts, 1997), enabling the variable to be estimated at a very fine scale while preserving the original point support. The kriged point estimates could be averaged over the larger support of the raster variable. However, this is unsatisfactory because the averaging process changes the cumulative density function (CDF) of the ground-measured variable and thus also the bivariate distribution function (BDF) with the remotely sensed variable. The CDF calculated on the larger support will have a smaller variance than the 'true' CDF and this will also affect the BDF.

The first- and second-order statistical moments of a random variable on support B , $Z(B)$, are related to those of a variable on a point support, $Z(s)$ in a domain D , by the following relations (Castrignanò and Buttafuoco, 2020):

$$E(Z(s)) = \mu, \text{ then } E(Z(B)) = \mu \quad (2)$$

where μ is the expected value of point and block variables, and

$$\bar{C}(B_i, B_j) = \text{cov}(Z(B_i), Z(B_j)) = \frac{1}{|B_i||B_j|} \int_{B_i} \int_{B_j} C(s, u) ds du \quad (3)$$

where $C(s, u) = \text{cov}[Z(s), Z(u)]$, $u, s \in D$, is the covariance of the variable on a point support.

The covariance on the block support, $\bar{C}$, depends not only on the covariance on the point support, but also on the support B . The relationship between the covariance on block support B and that on the point support s is a fundamental issue in the solution of the change of support problem. Eq. (3) was theoretically derived by Journel and Huijbregts (1978) and allows the transfer from the point variogram to the block variogram. The latter is calculated at large distances from the former by subtracting a term that can be interpreted as the variance of the block:

$$\bar{\gamma}_B(h) = \gamma(h) - \bar{\gamma}(B, B) \quad (4)$$

where $\bar{\gamma}_B(h)$ is the variogram on block support, $\gamma(h)$ is that on point support, and $\bar{\gamma}(B, B)$ is the mean value of the variogram within the block and is calculated as the average value of the point-support variogram between two arbitrary points within block B . To obtain the block support covariances (or semivariances), the point support covariances $C(s, u)$ (or semivariances) must be known or estimated from the available point-support data. The block-averaged semivariance is obtained by discretizing the block into points and then calculating the arithmetic mean of the point semivariance. The process of deriving the block semivariance or variogram from the point variogram is called regularization, while the reverse process (from block to point) is called de-regularization (see Fig. 4).

When point-support data are not available, one can resort to an iterative procedure (Goovaerts, 2008), which searches for the point support model by minimizing the difference between the theoretical regularized variogram model and the model adapted to the data on block support.

Once a satisfactory point model of the variogram has been fitted, it can be regularized to any pixel size (Eq. 4). This will enable one to jointly analyze (data fusion) a virtually infinite number of covariates from heterogeneous sources of information with any support. Eq. (4) thus provides a geostatistical method for rescaling the variogram model rather than the data. The model fitted to the regularized variogram may differ from that for point support in both type and parameters. Therefore, it is possible to evaluate the effect of change in size, shape, and orientation of the support on the nature and scale of the estimated spatial variation. Moreover, Eq. (4) shows that the effect of regularization is to remove the within-block variance, i.e. small-scale or high-frequency variation. If there is considerable variation at a small scale compared to the support, then much variation will be removed by upscaling. Conversely, if the variation at a scale greater than the support is large, only a small proportion of the total variance will be suppressed. It is worth emphasizing that any variation in the measurement support has a quantifiable effect on the understanding of the process.

Fig. 4 An example to illustrate how change of support affects the variogram.

Geostatistical fusion of heterogeneous spatial data

The modern era is marked by a large availability of data from different sources with diverse spatial, temporal, and statistical characteristics. It is therefore very common for spatial models to use a variety of data as inputs, among which the ones recorded with different proximal and or remote sensors. Multi-source data imply the presence of multiple-scales as intrinsic to the information flow (Zhang et al., 2015), however, the process of integrating multiple scales and fusing heterogeneous information is not at all trivial. To take advantage of the complementary features of the different types of data, they should be combined in an efficient and statistically robust way. A solution to this problem can be sought by resorting to multivariate geostatistics, although this method is not the only one that can be found in the literature.

Multivariate spatial correlations can be modeled within the scope of the linear model of co-regionalization (LMC) (Webster and Oliver, 2007), which considers all n studied variables as the manifestation of the same independent physical processes, acting over a number (N_S) of spatial scales u . The $n(n+1)/2$ simple and cross variograms of the variables are modeled by linear combinations of N_S standardized variograms of unit sill, $g^u(h)$ which are the same for all variables for each scale u .

Spatial modeling with a change of support is commonly treated in geostatistics by applying block kriging, which is one of the traditional geostatistical interpolation methods to tackle this problem. From point support observations, block kriging can be used to predict the average values at a larger support, accounting for the block's attributes (size, shape, and orientation). The main difference between block kriging and point kriging is the calculation of the block-to-point covariance:

$$\overline{C}(B, \mathbf{x}_z) = \text{cov}(Z(B), Z(\mathbf{x}_z)) = \frac{\int_B C(\mathbf{u}, \mathbf{x}_z) d\mathbf{u}}{|B|}, \quad (5)$$

where $|B|$ is the measure of the block (spatial support), $\mathbf{x}_z$ the point location and $C(\cdot)$ is the point-to-point covariance. For multivariate data sets, cokriging rather than kriging is used, which enables co-estimation of poorly sampled variables from secondary more exhaustive information related to the target variables (Webster and Oliver, 2007).

Although cokriging equations are valid regardless of the support of the data, it is essential to consider the different supports in calculating the autocovariance and cross-covariance functions for valid inference (Castrignanò et al., 2018). Once a consistent model for the point covariance functions is estimated, block cokriging can be applied by replacing the covariances in punctual cokriging with their block-averaged counterparts through regularization of the covariance (variogram).

Multivariate factorial kriging is a variant of cokriging (Castrignanò et al., 2000; Wackernagel, 2003), which aims to estimate the different sources of spatial variation common to a set of variables. This amounts to calculating N_S (number of scales in the LMC) sets of ortho-normal regionalized factors, one set for each spatial scale, as a linear combination of the n variables for each factor. Mapping the regionalized factors is a very effective way to synthesize the major features of the multivariate data set at the different spatial scales identified in nested experimental variograms (Castrignanò et al., 2017, 2018).

Application of geostatistics to multi-scaling and change of support in spatial modeling

The previous sections have shown the existence of a relationship between spatial dependence, as described by a variogram, and a set of spatial scales relevant to spatial modeling. Therefore, the variogram(s) of any variable, or set of variables in a multivariate approach, can be used as an analytical tool for multiscale spatial modeling in geostatistics. A key question in spatial modeling is whether it is more appropriate to use a single most relevant spatial scale or rather provide multiple representations of the same scene at different scales, corresponding to those identified by the spatial data analysis. We believe that it is more reliable to produce multiscale descriptions because the spatial relationships among variables vary as a function of scale. Once the overall spatial variance has been decomposed into its various spatial components, the one specific to the phenomenon under study could be selected (Manziona and Castrignanò, 2019; Castrignanò et al., 2021; Buttafuoco et al., 2021).

Case study

The case study aims to explore the use of multispectral data from an unmanned aerial vehicle (UAV) on-board radiometer combined with sparse point data from a ground-based sample to improve the prediction accuracy of soil textural components. The site was in a relatively flat olive grove in southern Italy consisting of centenarian trees. The planting pattern is wide and somewhat irregular leaving large portions of soil bare or occupied by weeds as the weather evolves. This field has loose gravel-free soil, classified as a Calcic Haploxeralf, fine, mixed, thermic (USDA classification) and Calci-Chromic (Endoleptic) L (WRB classification).

Regular plowing and mulching were carried out for weed control, and no irrigation was applied. Topsoil (0–0.20 m) samples were collected in three different places near each of the 61 olive trees, within a 1-m by 1-m square, and mixed to produce a single composite sample (Fig. 5). Soil texture was determined with the pipette method in the laboratory to determine the silt and clay contents (%) of the soil samples. Sand content was calculated as the complement to 100 of the sum of silt and clay contents.

Fig. 5 Locations of topsoil samples (red dots) collected near each of the 61 trees of the olive grove.

Acquisition of reflected electromagnetic radiation with UAV

The aerial survey was conducted with a very light quadcopter (DJI Mavic Pro drone), equipped with an on-board global navigation satellite system (GNSS) and able to perform programmed missions over waypoints, on August 2nd, 2019. This date was chosen because the soil appeared dry and mostly free of weeds. A custom-designed payload tray carried the multispectral sensor Parrot Sequoia camera, which captures four-band spectral images in green (550 ± 20 nm), red (660 ± 20 nm), red-edge (735 ± 5 nm), and near-infrared (790 ± 20 nm) at a very fine spatial resolution of 0.07-m.

Before geostatistical processing, the multispectral pixels referring only to the soil were selected for use as auxiliary high-density information in the data fusion process. The selection of soil pixels was done by applying a supervised classification with ENVI (ENvironment for Visualizing Images) 5.1 software (Harris Geospatial).

Geostatistical analysis

To use the selected multispectral data as exhaustive (i.e., known everywhere) information, they were interpolated beforehand to the nodes of a predefined estimation grid.

To merge the multispectral data (0.07 m $\times$ 0.07 m support) with the soil sample data (1-m by 1-m support), it was necessary to transform them to the same support through the change of support procedures. Therefore, block cokriging was used as the interpolation technique for the four-band data. All the multivariate geostatistical analyses were undertaken using Gaussian transformed data standardized to mean 0 and variance 1. The spatial correlation structure of the multi-band UAV data was analyzed by adapting a linear model of co-regionalization (LMC) to the matrix of the four-band reflectance experimental variograms. Each variogram on a point (centimetric) support was then regularized to a corresponding variogram on the 1-m by 1-m block support, by discretizing each block into a number (10) of equal cells.

Block cokriging was used on the multi-band transformed data to produce estimates both at the nodes of a regular 1-m mesh interpolation grid, and at the locations of the soil samples to create the complete coregionalization data set. Both types of estimates were needed in the subsequent data fusion phase.

Multi-collocated cokriging was applied to the fused data set of the drone and soil sample data using the gridded auxiliary variables previously interpolated. Multi-collocated cokriging is a simplified version of full cokriging that uses the auxiliary gridded variables only at the interpolation point and at all locations where the soil variables are available. This approach is required when the auxiliary variables are particularly numerous for which resolution of the cokriging system is very time-consuming or even impossible.

The same LMC fitted for multi-collocated cokriging was also used in multi-collocated factorial cokriging analysis to extract a few synthetic scale-dependent indicators to be used for soil partitioning. Factorial cokriging is very effective in decomposing the total spatial variance of the fused data into its spatial components and for identifying the main scales of variation.

Mapping the retained scale-dependent regionalized factors, which explain most of the variance at the specific scales, provides a powerful and synthetic way to show the spatial relationships among several variables at the different spatial scales. Each map is a snapshot of the study scene at the particular scale chosen, disregarding all others (Castrignanò et al., 2017). The approach can be

used in soil science to produce a scale-dependent partition of the study area into homogeneous management zones. All geostatistical analyses were performed using the software ISATIS (Geovariances, France, 2018).

Results

There were 2,032,972 multi-spectral pixels selected as attributable to the soil only and to be fused with soil sample data. Table 1 gives the basic statistics of the four-band reflectance. They all have a skewness value greater than 1, which indicates that the data distributions were not centered.

To calculate the experimental variograms of the Gaussian transformed drone data, it was necessary to reduce the number of pixels by superimposing a regular 1-m grid on the study area and by choosing one point within each cell. The procedure retained 12,974 pixels. An LMC was jointly fitted to the ensemble of direct and cross-experimental variograms of the drone-transformed data; it comprised three basic spatial structures: a nugget effect, a spherical model with a range of 7.78 m, and a spherical model with a range of 76.59 m. Cross-validation showed that the model fitting was reasonable for all four variables. The total spatial variance was then divided into three components: the spatially uncorrelated error, accounting for 43%, and two spatially correlated components: the former at a shorter range accounting for 43% of the total spatial variance, and the latter at a longer range, accounting for 14%. These results show that almost all of the variation described by the drone data alone (approximately 86%) is attributable to variation over distances less than 8 m, approximately the average canopy size of an olive tree. The high-density information was used for downscaling the information on soil texture components from the sparse sampling at 61 locations to a sampling scale of about 15 m on average.

To fuse the drone data with soil sample data, all point experimental direct and cross-variograms were regularized on a 1-m $\times$ 1-m block. A block LMC was then fitted (Fig. 6), including the following basic spatial structures: a nugget effect, a spherical model with a range of 10.93 m, and a spherical model with a range of 77.59 m. The proportions of total spatial variance explained by the three components were: 41% for the nugget effect; 33% for short-range structure; 26% for long-range structure.

A comparison of the block LMC with the corresponding point LMC shows that the mathematical form of the basic structure has not changed, with only a slight increase in the ranges. However, the proportions of total variance explained by nugget and short-range structures were reduced in favor of an increase in the variance explained by the longer-range structure.

An expected significant reduction occurred in the total spatial variance from 5.26 for the point model to 2.93 for the block model (about 56%). The effect of upscaling was therefore a decrease in the spatially uncorrelated error (nugget effect) and total spatial variance.

From this point onwards all geostatistical analyses were based on the complete coregionalization data set, comprising the clay and silt variables, and the block cokriged estimates of the drone-transformed variables at the 61 locations. The variables were transformed to standardized Gaussian variables for multivariate analysis and an LMC was fitted to the matrix of experimental variograms including: nugget effect, a spherical model with a range of 16.79 m, and a spherical model with a range of 98.7 m, which explained 38, 30 and 32% of the total variance, respectively.

The spatially uncorrelated component is still quite large despite fusion with the drone data. To reduce this there is a need to intensify point sampling of the soil. The two spatial scales identified might be related to factors associated with the olive trees and intrinsic variation associated with the granulometric and structural soil properties.

Fig. 7 shows that all the direct variograms are reasonably structured, although for silt and clay the nugget effect remains rather large due to the coarse sampling. However, the spatial correlations between the textural and drone variables (cross-variograms) are quite weak, which can be deduced from the distance between the model (bold line) and the dashed line representing the intrinsic correlation (maximum spatial correlation) (Wackernagel, 2003).

There may be two main causes for the above situation. The first is the large difference between the pixel size of the drone data of 0.07 m, although upscaled to 1 m, and the sampling interval of the soil data of the order of tens of meters. The second cause may be the choice of broadband radiometer, which explored a wavelength range (approximately 530–810 nm) (vis–NIR), that does not correlate strongly with the soil textural properties, which mostly affect the 1000–2500 nm range (SWIR) of soil reflectance spectra (Riefole et al., 2022).

Fig. 8 shows the maps of silt and clay obtained by cokriging and that of sand obtained by the difference. A common feature of these maps is the prevalence of short-range variation. However, it is possible to distinguish some degree of spatial association in the

Table 1 Basic statistics of the four band reflectances (NIR, near-infrared).

Variable	Count	Minimum	Maximum	Mean	Median	Std. Dev.	Skewness	Kurtosis
Green	2,032,972	0.027	0.256	0.098	0.094	0.018	1.56	7.73
Red	2,032,904	0.021	0.362	0.133	0.128	0.030	1.35	6.33
Red_edge	2,032,972	0.028	0.401	0.183	0.177	0.034	1.15	5.78
NIR	2,032,972	0.032	0.558	0.235	0.228	0.041	1.08	5.65

Fig. 6 Block LMC: dots: experimental variogram; bold line: model; dashed line: intrinsic correlation.

texture data whereby the particle size is predominantly finer in the north whereas the south has the largest sand content. This partitioning of the field was formerly detected with a GPR survey that revealed a large central–southern zone in which the reflected radar signal was stronger (Riefole et al., 2022).

To partition the soil into homogenous units, the first regionalized factor for the longer scale only (>98 m) was retained because it had an eigenvalue greater than 1 (2.06). In Fig. 9 this factor is represented using an isofrequency color scale with three classes.

The silt and clay variables have a negative influence on the factor, therefore, the red areas are those with finer grain composition, while the larger sand contents occur in the southeast and west.

For comparison, Fig. 10 shows the silt and clay maps obtained by a univariate approach.

Effectively, the latter seems less variable than those obtained by the fusion approach. The differences are not large because of the weak spatial correlation between the drone and sample data. The short-range variation introduced by the radiometric data could be due to properties (such as the presence of weeds) not strictly related to soil texture. Therefore, we recommend that for data fusion auxiliary variables should be chosen appropriately with supports not very different from those of the variable of interest. Otherwise, techniques of change of support should be applied. In addition, if radiometer data are used, the spectral ranges should include those bands that experimental results have verified to be correlated with specific (chemical and or physical) soil properties. Remote and proximal sensing data can be used as auxiliary variables to effectively support sparse soil sample data, but they cannot completely replace data from direct sampling.

Fig. 7 The LMC of the whole data set of coregionalization (fusion).

Concluding remarks

Scale is a topic of great interest to various categories of environmental scientists for a multitude of reasons. Researchers often select a spatial scale, or rather a range of scales of measurement, to provide information on spatial variation. It is crucial to gain knowledge about the spatial structure of the property(ies) under study. This can be achieved by calculating the direct experimental variogram or the set of direct and cross experimental variograms in the multivariate approach, to determine the scale(s) of spatial variation in the sample data. If the size of sample support does not match the supports of other data sources, it is possible, once an LMC (linear model of correlation) has been fitted, to regularize (upscaling) or de-regularize (downscaling) the spatial model geostatistically to predict variation in the variable(s) at its/their actual scale(s) (change of support). This approach means that it is possible to obtain such information without having to repeat the measurements with different support, with the need only to modify the spatial functions (covariance/variogram).

Fig. 8 The cokriging maps of silt (A), clay (B), and that derived for sand (C).

Fig. 9 The map of the first regionalized factor for the longer scale (98 m).

When the physical relations among variables are known, we recommend that they are integrated into the spatial model. This can be achieved by combining geostatistics with process-based modeling so that spatial dependence and spatial heterogeneity can be incorporated into mechanistic models, which describe the dynamics of the underlying processes that control spatial information.

An effective integration would improve understanding of the interaction between spatial dependence and the factors controlling multiple scales of spatial variation. Geostatistics and process models should form a unified framework for scale modeling and change of scale in controlling the flow of spatial information from measurement through data analysis to applications.

Fig. 10 The maps of silt (A) and clay (B) obtained by the univariate approach.

Last, but certainly not least, is the problem of uncertainty and its relation to scale (Heuvelink, 2014). Uncertainty is present everywhere in spatial information and it has the effect of weakening and causing bias in spatial relationships. Uncertainty has complex interactions with scale, as demonstrated in geostatistics where the variance of (co)kriging estimates depends explicitly on the nested variogram model. It has also been shown how the variance of a variable is a function of support.

Uncertainty in models has traditionally been treated with methods of error analysis based on error propagation. These assume spatial independence in error distribution, while spatial dependence is characteristic of spatial data and spatial errors. A better strategy for modeling error is based on stochastic simulation (Chilès and Delfiner, 2012), which makes it possible to generate a very large number of equally probable realizations in which the intrinsic spatial structure of the scene under study is reproduced, and the sample data are honored at their locations in the case of conditional simulation. In this respect, geostatistical simulation with its various procedures can make a valuable contribution to the assessment of the interaction between scale and uncertainty.

Abstract

A sound sampling design is essential for the collection of data to support reliable scientific inference and decision making for management and policy. What counts as a sound design depends on the problem of interest, and the nature of the statistical inference that is required. Two broad aims can be distinguished, estimating the mean or total of a population or several subpopulations and mapping. For estimating (sub)population means or totals probability sampling and design-based or model-assisted estimation is most appropriate, whereas for mapping probability sampling is not required and there is scope to optimize the sampling pattern.

Key points

- Probability sampling is required for design-based estimation and model-assisted estimation of (sub)population parameters.
- For mapping probability sampling is not required, but still can be advantageous.
- Inclusion probabilities of population units need not be equal.
- Covariates can be exploited at the stage of designing a probability sample and/or at the estimation stage.
- Balanced sampling and well-spread sampling have potentials for soil survey.
- Geometric sampling designs for mapping do not require a prior model of the spatial variation.
- A prior model of the spatial variation can be used to optimize the sample size and/or the sampling pattern.

Introduction

To survey the soil data must be collected from the region of interest. We cannot afford to observe the soil everywhere, so in one way or another we must select locations where these observations will be done. Questions then, among others, are: (i) How do we define the elementary sampling units, are these points or areal sampling units, and in the case of areal sampling units, what is their shape and size? (ii) To what depth do we want to sample? (iii) How many locations should we select?, and (iv) How should we select these locations? This chapter focuses on the last two questions: the most relevant sampling designs for soil survey and methods for the determination of sample size are reviewed. For a more comprehensive text on how to design a soil sampling scheme I refer to [de Gruijter et al. \(2006\)](#). For more details on random sampling designs I recommend the following textbooks: [Cochran \(1977\)](#), [Särndal et al. \(1992\)](#), and [Lohr \(1999\)](#). [Brus \(2022\)](#) describes how the sampling designs and the estimation procedures can be implemented in the programming language R.

Probability sampling versus non-probability sampling

Sampling locations can be selected randomly or non-randomly. The term random sampling is often used for arbitrary or haphazard sampling, i.e. sampling without a specific purpose in mind. To avoid confusion in the sampling literature the terms probability sampling and non-probability sampling are used. Probability sampling is random sampling using a (pseudo) random number generator, such that all population units have a positive probability of being selected. Furthermore, these probabilities, referred to as the inclusion probabilities, must be known, at least for the selected units. As we will see hereafter, the inclusion probabilities are used in estimating population parameters such as the population mean, population total, or population proportion.

In non-probability sampling no such random number generator is used. Examples of non-probability sampling are (i) convenience sampling, i.e. sampling at places that are easy to access, e.g. along roads; (ii) arbitrary sampling, i.e. sampling without a specific purpose in mind; and (iii) targeted sampling, e.g. at sites suspected of soil pollution or at sites so that some criterion is minimized.

The choice between probability or non-probability sampling is closely connected with the choice between the design-based, model-assisted, or model-based approach for sampling and statistical inference. In the design-based approach and model-assisted approach units are selected by probability sampling ([Table 1](#)). Statistical inference is based on the sampling distribution of an estimator, which is determined by the sampling design. In the design-based approach no model is used in estimation (design-based inference). In the model-assisted approach a model is used to derive an efficient estimator, but statistical inference is not based on the model rather on the sampling distribution of the estimator. In the model-based approach a statistical model is used in prediction, i.e. a model with a random error term, for example a regression model or a kriging model. As the model already contains a random error term, probability sampling is not required in this approach. Statistical inference is fully based on the model distribution of the predictor. In contrast to the model-assisted approach, the model-based approach fully relies on the statistical model for statistical inference. This approach is also referred to as the model-dependent approach.

Which statistical approach is best depends largely on the aim of the survey. In general the following aims can be distinguished:

1. estimating parameters for the population;
2. estimating parameters for several subpopulations; and
3. mapping the study variable.

When the aim is to map the study variable, a model-based approach is the most natural option. This implies that for this aim probability sampling is not necessarily required. In principle, both approaches are suitable for estimating (sub)population parameters. The more subpopulations are distinguished, the more attractive a model-based approach becomes. Model-based estimates of the subpopulation means or totals are potentially more accurate (depending on how good the model is) than model-free design-based estimates. On the other hand, an advantage of design-based estimation is that an objective assessment of the uncertainty of the estimated mean or total is warranted, and that the coverage of confidence intervals is (almost) correct.

A probability sample can also be used in model-based inference. This flexibility can be attractive when we have a dual aim, mapping as well as estimation of parameters of (sub)populations. The balanced sample with geographical spreading shown in [Fig. 8](#) might be a good candidate for this dual aim. When units are not selected by probability sampling, model-free design-based estimation is impossible, and model-based prediction is the only option.

Table 1 Statistical approaches for sampling and inference.

<i>Approach</i>	<i>Sampling</i>	<i>Inference</i>
Design-based	Probability sampling required	Based on sampling distribution of estimator; no model used
Model-assisted	Probability sampling required	Based on sampling distribution of estimator; model used to derive estimator
Model-based	Probability sampling not required	Based on model distribution of predictor

Finally a warning. Do not be misled by publications stating that the design-based approach assumes that data are independent, and for that reason should not be used to sample populations showing spatial correlation. This is a persistent misconception: no such assumption is made and probability sampling is perfectly fine to sample such populations. See Brus (2021) for the details.

Probability sampling for estimating population parameters

Sampling designs

To estimate a population parameter probability sampling is most appropriate. The probability that a unit is included in the sample, in short the inclusion probability of that unit, can be calculated as the sum of the selection probabilities over all samples that can be selected with a given sampling design and that contain this unit. The formula is given by:

$$\pi_k = \sum_{S \ni k} p(S), \quad (1)$$

where $S \ni k$ indicates that the sum is over all samples that contain unit k , and $p(S)$ is the selection probability of sample S . $p(\cdot)$ is called the sampling design. It is a function that assigns a probability to every possible sample (subset of population units) that can be selected with a given sample selection scheme (sampling algorithm). For instance, it can be shown that for simple random sampling without replacement from a finite population the inclusion probability of every population unit is n/N , with n the sample size and N the total number of units in the population.

A common misunderstanding is that with probability sampling the inclusion probabilities must be equal. Sampling with unequal inclusion probabilities can be more efficient than with equal probabilities. Unequal probability sampling is not a problem as long as the inclusion probabilities are known and proper formulas are used for estimation.

There are many schemes for selecting a probability sample. The following sampling designs are described and illustrated in this chapter:

1. simple random sampling;
2. stratified random sampling;
3. systematic random sampling;
4. cluster random sampling;
5. balanced and well-spread sampling.

In stratified random sampling, balanced sampling, and well-spread sampling one or more ancillary variables are used in the random selection of the units. If these ancillary variables are related to the study variable, these sampling designs may provide a more precise estimate of a population parameter than simple random sampling at equal sample sizes.

The first four sampling designs will be illustrated with the Voorst study area in the Netherlands. Samples of the topsoil were collected at 132 points, which were analyzed for soil organic matter (SOM) concentrations (in g kg^{-1} dry soil) in a laboratory. The data were used in conditional geostatistical simulation of natural logarithms of the SOM concentration on a $25 \text{ m} \times 25 \text{ m}$ grid, followed by backtransformation. Fig. 1 shows the simulated map of SOM. This map is treated as the groundtruth in sampling experiments. At any location in Voorst the true SOM concentration is known, so that for any probability sample the mean SOM concentration can be estimated and compared to the true mean SOM concentration.

In the next sections I assume that the population units are points. The population is then infinite as the soil in an area is a continuum. With areal sampling units, for example circular sampling plots, that are allowed to overlap the population is also infinite. With infinite populations the distinction between without and with replacement sampling becomes immaterial and inclusion probabilities become inclusion probability densities. For instance, in simple random sampling of points from an infinite population the inclusion probability density is n/A for all points, where A is the area of the study area.

Fig. 1 Simulated map of the SOM concentration (g kg^{-1}) in Voorst.

Estimators

To estimate a population parameter several estimators are available: (i) the Horvitz-Thompson estimator; (ii) the Hansen-Hurwitz estimator; (iii) the ratio estimator; and (iv) model-assisted estimators.

Horvitz-Thompson estimator

For any probability sampling design the population total can be estimated as a weighted sum of the observations (measurements) of the study variable on the selected population units:

$$\hat{t}_{\pi}(z) = \sum_{k \in S} w_k z_k, \quad (2)$$

with S the sample, z_k the observed study variable for unit k , and w_k the design weight attached to unit k :

$$w_k = \frac{1}{\pi_k}, \quad (3)$$

with π_k the inclusion probability density of unit k . Hereafter the Horvitz-Thompson estimator is referred to in short as the π estimator. The π estimator for the population mean is simply obtained by dividing it by the size of the population, N for finite populations, A for infinite populations.

Hansen-Hurwitz estimator

In sampling finite populations, units can be selected with or without replacement. In sampling with replacement after each draw the selected unit is replaced. As a consequence a unit can be selected more than once. Sampling with replacement is less efficient than sampling without replacement. If a population unit is selected in a given draw, there is no additional information in this unit if it is selected again. One reason that sampling with replacement is still used is that it is easier to implement.

The most common estimator used for sampling with replacement is the Hansen-Hurwitz estimator, referred to as the pwr estimator hereafter. With direct unit sampling, i.e. sampling of individual population units, the pwr estimator of the population total is

$$\hat{t}_{\text{pwr}}(z) = \frac{1}{n} \sum_{k \in S} \frac{z_k}{p_k}, \quad (4)$$

with p_k the draw-by-draw selection probability of population unit k . In the pwr estimator observations of the selected units are expanded by the draw-by-draw selection probability. For example, in simple random sampling with replacement the draw-by-draw selection probability p of each unit is $1/N$. If we select only one unit k , the population total can be estimated by the observation of that unit divided by p , $\hat{t}(z) = z_k/p_k = Nz_k$. If we repeat this n times, it results in n estimated population totals. The pwr estimator is the average of these n elementary estimates. If a unit occurs multiple times in the sample S , this unit provides multiple elementary estimates of the population total.

Sampling with replacement can also be applied at the level of clusters of population units as in cluster random sampling and two-stage cluster random sampling. If the clusters are selected with probabilities proportional to their size and with replacement, estimation of the population mean, proportion or total is rather simple. This is a second reason why sampling with replacement can be attractive. With cluster sampling the pwr estimator of the population total is

$$\hat{t}_{\text{pwr}}(z) = \frac{1}{n} \sum_{j \in S} \frac{t_j(z)}{p_j}, \quad (5)$$

with $t_j(z)$ the total of the cluster selected in the j th draw.

Ratio estimator

With some sampling designs the sample size is not fixed but varies among samples selected with that design. An example is systematic random sampling from an irregular area. In this case an alternative estimator of the population mean is the ratio estimator. In the ratio estimator the π estimator of the population total is divided by the π estimator of the population size:

$$\hat{z}_{\text{ratio}} = \frac{\sum_{k \in S} w_k z_k}{\sum_{k \in S} w_k}. \quad (6)$$

The ratio estimator can also be efficient for sampling designs in which the points are selected with probabilities proportional to an ancillary variable.

Model-assisted estimators

The estimators described in the previous subsections use only data of the study variable. Over the past decades numerous large data sets have become available, such as those obtained by satellites and proximal sensors. These data sets may contain valuable information about study variables, so that they can be used to estimate global or local means and totals for these variables. Various

estimators have been developed that exploit these ancillary variables. They are jointly referred to as model-assisted estimators. A well-known example of this is the regression estimator:

$$\hat{z}_{\text{regr}} = \hat{z}_{\pi} + \sum_{j=1}^J \hat{b}_j (\bar{x}_j - \hat{x}_{j,\pi}), \quad (7)$$

with $\hat{z}_{\pi}$ and $\hat{x}_{j,\pi}$ the π estimator of the study variable and the j th covariate, respectively, $\bar{x}_j$ the population mean of the j th covariate, and $\hat{b}_j$ the estimated slope coefficient associated with the j th covariate, estimated by

$$\hat{\mathbf{b}} = \left(\sum_{k \in S} \mathbf{x}_k \mathbf{x}_k^T \right)^{-1} \sum_{k \in S} \mathbf{x}_k z_k. \quad (8)$$

A wide range of model-assisted estimators is available, see Brus (2022) for an overview. In situations where we have numerous covariates, and we do not want to rely on a linear relation between the study variable and these covariates, model-assisted estimators that build on machine learning techniques can be a good option.

An interesting application of model-assisted estimators is the estimation of the mean (total) of “small” subpopulations, i.e. subpopulations with a sample size that is too small to obtain a reliable estimate of the mean (total).

Simple random sampling

Simple random sampling is the most basic type of sampling design. All points have the same inclusion probability density. In addition, all samples of n points have the same probability of being selected. Fig. 2 shows a simple random sample of 40 points from the Voorst study area.

Working out the π estimator (Eq. 2) for simple random sampling yields the unweighted sample mean $\bar{z}_S$. The π estimate for the selected simple random sample of Fig. 2 is 93.3 g kg⁻¹.

The variance of the π estimator of the mean can be estimated by

$$\hat{V}(\hat{z}) = \frac{\hat{S}^2(z)}{n}, \quad (9)$$

with $\hat{S}^2(z)$ the estimated population variance:

$$\hat{S}^2(z) = \frac{1}{n-1} \sum_{k \in S} (z_k - \bar{z}_S)^2. \quad (10)$$

An estimate of the standard error is obtained by taking the square root of the variance estimate. The standard error has the same dimension as the study variable, and therefore is more intelligible than the variance. However, contrary to the variance estimator the estimator of the standard error is not unbiased. For the selected sample the estimated standard error is 9.604 g kg⁻¹.

Stratified simple random sampling

In stratified random sampling the study area is partitioned into subareas, referred to as strata. If the strata explain part of the spatial variation of the study variable, stratified random sampling is more efficient than simple random sampling, i.e. the π estimator of the population mean or total is more precise than the π estimator with simple random sampling and an equal number of points.

Fig. 3 shows a stratified random sample from the Voorst study area. Here, strata are combinations of soil types and land use classes. The points within the strata are selected by simple random sampling, so this is an example of a stratified simple random sample.

Fig. 2 Simple random sample of size 40 from the Voorst study area, The Netherlands.

Fig. 3 Stratified simple random sample of size 40 from the Voorst study area, The Netherlands. Strata are combinations of soil class and land use.

Working out the π estimator of the population mean for this sampling design yields

$$\hat{z} = \sum_{h=1}^H w_h \hat{z}_h, \quad (11)$$

where H is the number of strata, w_h is the relative size (area) of stratum h (stratum weight): $w_h = A_h/A$ (A_h is the area of stratum h), and $\hat{z}_h$ is the estimated mean of stratum h , estimated by the sample mean for stratum h .

The variance of the π estimator of the mean can be estimated by

$$\hat{V}(\hat{z}) = \sum_{h=1}^H w_h^2 \frac{\hat{S}_h^2(z)}{n_h}, \quad (12)$$

with $\hat{S}_h^2(z)$ the estimated variance of z within stratum h and n_h the sample size of stratum h .

The design effect, defined as the ratio of the variance of the estimator of the mean with a design under study to the variance with simple random sampling, quantifies the relative efficiency of a design compared to simple random sampling. For design effects smaller than 1, the design under study is more efficient than simple random sampling. In the case of the Voorst study area, for stratified simple random sampling and proportional allocation (see hereafter) the design effect is 0.763. This implies that with simple random sampling we need $1/0.763 = 1.310$ times more sampling points than with stratified simple random sampling to obtain the same standard error.

Allocation of sample size to strata

After we have decided on the total sample size n , we must decide how to apportion the points to the strata. It is reasonable to allocate more sampling points to large strata and fewer to small strata. The simplest way to achieve this is proportional allocation, in which the stratum sample sizes are proportional to A_h .

If we have prior information on the variance of the study variable within the strata, then it makes sense to account for differences in variance. Heterogeneous strata should receive more sampling points than homogeneous strata. This leads to Neyman allocation in which the stratum sample sizes are proportional to $A_h S_h(z)$, with $S_h(z)$ the standard deviation of the study variable in stratum h .

Finally, the costs of sampling may differ among the strata. It can be relatively expensive to sample nearly inaccessible strata, and we do not want to sample many points there. This leads to optimal allocation in which the sample sizes are proportional to $(A_h S_h(z))/\sqrt{c_h}$, with c_h the cost per sampling point in stratum h .

Stratification

When we have a raster map of a quantitative covariate related to the study variable, strata can be constructed with the cum-root-f method using this covariate as a stratification variable. Raster cells with similar values for the covariate are grouped into a stratum. In cum-root-f stratification it is assumed that (after linear transformation) the covariate values are almost perfect predictions of the study variable, so that the prediction errors do not affect the stratification. Under this assumption the stratification is optimal.

If we have multiple maps of quantitative covariates, an option is to construct first homogeneous groups, referred to as clusters, of raster cells. The raster cells within a cluster are more similar to each other than to those in other clusters. Various clustering techniques are available, one of which is hard k -means.

Another option is to use the covariates as predictors in a regression model. The predictions of the study variable can then be used in cum-root-f stratification. The prediction errors are disregarded. The prediction error variances and covariances can be accounted for by the optimal spatial stratification method of de Gruijter et al. (2015).

In the absence of covariates we may still construct compact geographical strata. This can be done with the spatial coordinates of the raster cells as clustering variables in k -means. The geostrata improve the spreading of the sampling locations throughout the study area.

Systematic random sampling

A simple way of drawing a probability sample whose units are spread uniformly over the study area, is systematic random sampling. Systematic random sampling from a two-dimensional spatial population entails sampling on a regular grid, such as a square or

Fig. 4 Systematic random sample (square grid) from the Voorst study area, The Netherlands.

triangular grid. Quite a few countries in the world monitor the soil on a regular grid. The sample is well-suited for mapping. Furthermore, the sample data can be used in design-based estimation of (sub)population parameters. The geographical spreading of the sampling locations enhances the precision of the estimators. However, a disadvantage is that there is no unbiased estimator of the variance of the estimator of the population parameter.

Fig. 4 shows a systematic random sample of 40 points from the Voorst study area, The Netherlands. The origin of the square grid is selected randomly, the orientation is fixed. With systematic random sampling the sample size is random. We can control the expected sample size, i.e. the average sample over repeated random sampling, but for an individual sample the size may differ considerably from this expected sample size. With the grid spacing of Fig. 4 the sample size varies from 20 to 48.

With systematic random sampling the population mean can be estimated best by the ratio estimator, Eq. (6). For systematic random sampling the weights w_k are equal to $A/E[n]$, with $E[n]$ the expected sample size. With equal weights the ratio estimator is equal to the sample mean:

$$\hat{z}_{\text{ratio}} = \frac{1}{n} \sum_{k \in S} z_k. \quad (13)$$

The variance can be approximated only, for example by treating the sample as a simple random sample. This leads in general to overestimation of the variance. Alternatively, the sampling variance can be approximated by treating the systematic random sample as if it were a stratified simple random sample. The sampling units are clustered on the basis of their spatial coordinates into $H = n/2$ clusters (n even) or $H = (n-1)/2$ clusters (n odd). A third option is Matérn's method, see (Brus, 2022).

Systematic random sampling (in combination with the ratio estimator) is more efficient than simple random sampling. For the Voorst study area the design effect, quantified as the ratio of the variance of the ratio estimator of the mean with systematic random sampling to the variance with simple random sampling, equals 0.885. With simple random sampling we need 1.129 more sampling points to achieve an equal precision of the estimated mean.

Cluster random sampling

Figs. 5 and 6 show two cluster random samples from the Voorst study area. In Fig. 5 the clusters are E-W oriented transects within 1 km squares with an inter-point spacing of 100 m, whereas in Fig. 6 the clusters are 0.5 km squares, built-up areas, roads etc. are excluded. There is another important difference between the two cluster samples. In the first case all points of a selected cluster (transect) are observed, whereas in the second case a cluster is observed at a sample of points only. The first cluster sample is therefore also referred to as a one-stage cluster sample, and the second as a two-stage cluster sample. In two-stage cluster sampling the clusters are also referred to as primary sampling units (PSUs), and the points as secondary sampling units (SSUs).

In both cases the size of the clusters, i.e. the number of points, varies among the clusters. It is convenient to select the clusters with probabilities proportional to their size and with replacement (ppswr). Estimation of the population parameter is then straightforward (see hereafter). In the two-stage cluster random sample of Fig. 6 each time a PSU is selected, 10 points are selected by simple random sampling.

With ppswr sampling of clusters the population total can be estimated by the pwr estimator (Eq. 5). The draw-by-draw selection probability of a cluster for one-stage cluster random sampling is given by M_j/A , with M_j the number of points of cluster j , and A_j/A in

Fig. 5 Cluster random sample from the Voorst study area, The Netherlands, selected with probabilities proportional to size and with replacement (ppswr).

Fig. 6 Two-stage cluster random sample from the Voorst study area, The Netherlands. The primary sampling units (PSUs) are 0.5 km squares, built-up areas, roads, etc. are excluded. Four times a PSU is selected by ppswr. Each time a PSU is selected, 10 secondary sampling units (points) are selected from that PSU by simple random sampling.

two-stage cluster random sampling. This yields for one-stage cluster random sampling the following estimator for the population mean.

$$\hat{\bar{z}} = \frac{1}{n} \sum_{j \in S} \bar{z}_j, \quad (14)$$

with n the number of cluster draws and $\bar{z}_j$ the mean of cluster j . For two-stage cluster random sampling the cluster means $\bar{z}_j$ are replaced by the estimated cluster means $\hat{\bar{z}}_j$.

The variance of the pwr estimator of the mean can be estimated by

$$\hat{V}(\hat{\bar{z}}) = \frac{\hat{S}^2(\bar{z})}{n}, \quad (15)$$

where $\hat{S}^2(\bar{z})$ is the estimated variance of cluster means (the between-cluster variance):

$$\hat{S}^2(\bar{z}) = \frac{1}{n-1} \sum_{j \in S} (\bar{z}_j - \hat{\bar{z}})^2. \quad (16)$$

For two-stage cluster random sampling the estimated variance of cluster means $\hat{S}^2(\bar{z})$ is replaced by the estimated variance of estimated cluster means $\hat{S}^2(\hat{\bar{z}})$.

In both cases the sampling points are strongly spatially clustered. In general this leads to some redundant information about the population parameter. For the Voorst study area, -with one-stage cluster random sampling the design effect equals 2.82, and with two-stage cluster random sampling 3.19. So both designs are far less efficient than simple random sampling. For the Voorst study area cluster random sampling is certainly not a good idea. It can be an attractive sampling design if substantial time is needed to access the sampling points, and can be saved by clustering the points, think for instance of a continent-wide survey of the soil.

Balanced and well-spread sampling

Balanced sampling

In balanced sampling one or more covariates that are related to the study variable are exploited. A sample is balanced on a covariate if the sample mean equals the population mean of the covariate. A balanced sampling design is one that selects balanced samples. Simple random sampling is not a balanced sampling design because for many simple random samples the sample mean of the covariate is not equal to the population mean.

Fig. 7 shows a simulated population with a spatial trend from the lower-left corner to the upper-right corner. The study variable is therefore correlated with Easting and Northing. The figure shows two balanced samples of four units, one on Easting, and one on Easting and Northing. The sample mean of Easting is 10 (the population mean of Easting), and for the second balanced sample the mean of Northing also equals 10. I repeated the sampling 1000 times, using equal inclusion probabilities, and computed the variance of the estimated mean of the study variable, estimated by the sample mean. Using Easting as a balancing variable strongly reduced the variance of the π estimator (Table 2). Adding Northing as a balancing variable further reduced the variance.

In the above example equal inclusion probabilities are used, but this is not a requirement. A more general definition of a balanced sampling design is as follows. A sampling design is balanced on variable x when for all samples generated by the design the π estimate of the mean of x equals the true mean of x . Similarly to the regression estimator balanced sampling exploits the linear relation between the study variable and one or more covariates. When using the regression estimator this is done at the estimation stage, whereas balanced sampling does so at the sampling stage. With a perfectly balanced sample the second term in the regression estimator (see Eq. 7) which adjusts the π estimator, equals zero.

Fig. 8 shows a sample of size 100 from the Hunter Valley, NSW, Australia, balanced on topographic wetness index (TWI). Equal inclusion probabilities are used. The population mean of TWI equals 5.41, the sample mean equals 5.40.

Fig. 7 Sample balanced on Easting (E) and on Easting and Northing (E and N).

Table 2 Sampling variance of the n estimator of the mean for simple random sampling (SI) and balanced sampling of four units.

Sampling design	Balancing variables	Variance
SI	–	39.7
Balanced	Easting	14.4
Balanced	Easting and Northing	9.77

Fig. 8 Sample of 100 points from the Hunter Valley, NSW, Australia, balanced on topographic wetness index, without (left subfigure) and with geographical spreading.

Well-spread sampling

With balanced sampling the spreading of the sampling points in the space spanned by the balancing variables can be poor. For instance, in Fig. 7 the Easting coordinates of all units of a sample balanced on Easting can be equal or close to the population mean of 10. So, in this example balancing does not guarantee a good geographical spreading. Stated more generally, a balanced sample can be selected that shows strong clustering in the space spanned by the balancing variables. This clustering may inflate the standard error of the estimated population total and mean. Various sampling algorithms have been developed that avoid clustering of the sampling points in geographical or covariate space, such as generalized random tessellation stratification and the local pivotal method. Grafström and Tillé (2013) developed an algorithm for selecting probability samples that are both balanced and well-spread. Fig. 8 shows a sample obtained by using TWI in balancing and Easting and Northing as spreading variables.

Sample size determination

An important decision in designing sampling schemes is the number of points to select. If a certain budget is available for sampling, we can determine the affordable sample size from this budget. A costs model is then needed.

The alternative to deriving the affordable sample size from the budget is to start from a requirement based on the quality of the survey result obtained by statistical inference. The required sample size depends on the type of sampling design. With stratified random sampling we expect that we need fewer sampling units than for simple random sampling to estimate the population mean with the same precision, whereas with cluster random sampling in general we need more sampling units. To compute the sample size given some quality requirement, we may start with computing the required sample size for simple random sampling and then correct this sample size to account for the design effect.

The quality requirement can be expressed, for example, in terms of the standard error of the estimator or the length of a confidence interval. If we require that the length of the confidence interval of the population mean may not exceed a given limit $l_{\max}$, the required sample size for simple random sampling can be computed with

$$n = \left(u_{\alpha/2} \frac{S^*(z)}{l_{\max}/2} \right)^2. \quad (17)$$

with $u_{\alpha/2}$, the $(1 - \alpha/2)$ quantile of the standard normal distribution and $S^*(z)$ a prior estimate of the standard deviation of the study variable in the population.

A similar equation can be derived for the population proportion. Sample size determination (SSD) in this case requires a prior estimate of the population proportion itself.

The required sample size for testing a population mean with a two-sided alternative hypothesis can be computed by

$$n = \frac{S^2(z)}{\Delta^2} (u_{\alpha/2} + u_{\beta})^2, \quad (18)$$

with Δ the smallest relevant difference of the population mean from the test value, α the tolerable probability of a type I error, i.e. the probability of rejecting the null hypothesis when the population mean is equal to the test value, β the tolerable probability of a type II error, i.e. the probability of not rejecting the null hypothesis when the population mean is not equal to the test value, $u_{\alpha/2}$ as before, and u_{β} the $(1 - \beta)$ quantile of the standard normal distribution. The quantity $1 - \beta$ is the power of a test: the probability of correctly rejecting the null hypothesis. For a one-sided test, $u_{\alpha/2}$ must be replaced by u_{α} .

The SSD for testing a population proportion is not entirely straightforward. The power of a binomial test does not increase monotonically with the sample size. The graph shows a saw-toothed behavior. There are two options for sample size determination. The first is to compute the smallest sample size for which the power is larger than or equal to the required power $1 - \beta$. The alternative is to compute the smallest sample size for which the power is larger than or equal to $1 - \beta$ for all sample sizes larger than this.

Given an estimate of the design effect of an alternative sampling design, d_p , the required sample size for that design can be computed by

$$n_p = \sqrt{d_p} n_{SI}, \quad (19)$$

with n_{SI} the sample size for simple random sampling.

Bayesian approach for sample size determination

A serious drawback of the classical frequentist approach of SSD explained in the previous subsection is that the required sample sizes are sensitive to the so-called design parameters S^* and p^* (p^* is the prior estimate of the population proportion). We are rather uncertain about these parameters, and therefore it is attractive to replace a single value for these parameters by a probability distribution. This leads to the Bayesian approach for sample size determination. This Bayesian approach also offers the possibility of accommodating existing information about the population mean or proportion. Various Bayesian criteria for SSD are available, among other the average length criterion (ALC). This is the length of the highest posterior density interval with a coverage of $1 - \alpha$,

averaged over all possible data vectors that can be simulated with the prior distribution of the design parameter. The ALC is the Bayesian counterpart of the length of the confidence interval of the frequentist approach for SSD. For details I refer to Brus (2022).

Model-based optimization of probability sampling designs

If a statistical model is available, it can be used to predict the variance of an estimator of the population mean for any probability sampling design. This can be useful for SSD, optimizing parameters of a sampling design, for example the allocation of the total sample size to the strata with stratified simple random sampling, and for comparing alternative sampling design types. There are three approaches: analytical, simulation, and Bayesian. The variance predicted with a statistical model is sometimes referred to as the anticipated variance.

Analytical approach

In the analytical approach we assume that the mean is the same everywhere. The sampling variance of the π estimator of the mean is derived from mean semivariances within the study area and mean semivariances within the sample. Assuming isotropy, the mean semivariances are a function of the separation distance between pairs of points.

For any probability sampling design the sampling variance of the π estimator of the population mean can be predicted by

$$E_{\xi}\left\{V_p\left(\hat{\bar{z}}\right)\right\}=\bar{\gamma}-E_p\left(\mathbf{\lambda}^T\mathbf{\Gamma}_S\mathbf{\lambda}\right), \quad (20)$$

where $E_{\xi}(\cdot)$ is the statistical expectation over realizations from the model ξ , $E_p(\cdot)$ is the statistical expectation over repeated sampling with sampling design p , $V_p\left(\hat{\bar{z}}\right)$ is the variance of the π estimator of the population mean over repeated sampling with sampling design p , $\bar{\gamma}$ is the mean semivariance of the random variable at two randomly selected locations in the study area, $\mathbf{\lambda}$ is the vector of design-based weights of the units of a sample selected with design p , and $\mathbf{\Gamma}_S$ is the matrix of semivariances between the units of a sample S selected with design p .

This generic procedure is computationally demanding, but is the only option for complex spatial sampling designs. For basic sampling designs computing time can be saved by working out Eq. (20). For instance, for stratified simple random sampling the sampling variance can be predicted by

$$E_{\xi}\left\{V_{\text{STSI}}\left(\hat{\bar{z}}\right)\right\}=\sum_{h=1}^H w_h^2 \bar{\gamma}_h / n_h, \quad (21)$$

with H , w_h and n_h as before, and $\bar{\gamma}_h$ the mean semivariance of stratum h .

Simulation approach

The simulation approach for predicting the variance can also accommodate models in which the mean is a linear combination of covariates and/or spatial coordinates. Furthermore, this approach can be used to predict the sampling variance of the estimator of the mean of a trans-Gaussian variable, i.e. a random variable that can be transformed to a Gaussian variable. In the simulation approach many maps of the study variable are simulated, and each is used to compute the variance of an estimator of the population mean for the sampling design under study. The average of the variances over all simulated maps is a Monte Carlo approximation of the anticipated variance.

Bayesian approach

The model-based prediction of the variance of the design-based estimator of the population mean for a given sampling design is conditional on the model. If we change the model type or the model parameters, the predicted sampling variance also changes. In most situations we are quite uncertain about the model. Instead of using the best estimated model to predict the sampling variance as done in the previous sections, we may prefer to account for the uncertainty about the model parameters. This can be done through a Bayesian approach, in which legacy data are used to update a prior distribution of the model parameters to a posterior distribution. A sample from the posterior distribution of the model parameters is used one-by-one to predict the sampling variance. This results in a distribution of sampling variances which reflects our uncertainty about the sampling variance of the estimator of the population mean due to uncertainty about the model parameters. The mean or median of the distribution of sampling variances can be used as the predicted sampling variance.

Non-probability sampling for mapping

When the aim is map a variable using a statistical model of the spatial variation, probability sampling is not strictly required. This offers the opportunity of optimizing the sample pattern, i.e. the locations of the sampling points in the geographical and/or covariate space. Three groups of sampling designs for mapping can be distinguished: (i) geometric; (ii) adapted experimental; and (iii) model-based sampling designs. Examples of these three groups will be presented in the following sections.

Geometric sampling designs

Square and triangular grids are examples of geometric sampling designs; the sampling points show a regular, geometric spatial pattern. Contrary to systematic random sampling, there is no need to place the grid randomly on the study area. In other geometric sampling designs the spatial pattern is not perfectly regular. Yet these are classified as geometric sampling designs when the samples are obtained by minimizing some geometric criterion, i.e. a criterion defined in terms of distances between the sampling points and the nodes of a fine prediction grid discretizing the study area. If we use the mean of the squared shortest distance of the sampling points to the discretization nodes as a minimization criterion the clustering algorithm *k*-means can be used to compute the optimal spatial pattern. Fig. 9 shows a spatial coverage sample obtained by using the spatial coordinates of the raster cells in clustering, and a covariate space coverage sample using TWI, normalized difference vegetation index (NDVI) and elevation in clustering. In the latter case the covariates are scaled so that the covariates have equal weights in clustering.

Legacy data are easily accommodated in spatial coverage sampling and covariate space coverage sampling by using them as fixed cluster centers.

Adapted experimental designs

Experimental designs that are adapted for spatial surveys are the response surface and the Latin hypercube designs. Response surface experimental designs aim to find an optimum of the response within specified ranges of the factors. It is assumed that some type of low order regression model can be used to approximate accurately the relationship between the study variable and the factors. To make this experimental design suitable for observational research the covariates are decorrelated, using principal components analysis. In addition, spatial clustering of sampling points is avoided, so that we can safely assume that the residuals of the regression model are independent.

Latin hypercube sampling is used in designing, for instance, agricultural and computer experiments with numerous covariates and/or factors of which we want to study the effect on the output. With numerous covariates and/or levels per covariate/factor a full factorial design becomes unfeasible. A much cheaper alternative then is an experiment with for all covariates/factors just one observation per level.

Latin hypercube sampling for observational studies is coined as conditioned Latin hypercube sampling (cLHS). For each covariate a series of intervals (marginal strata) is defined. The breaks in the marginal strata are chosen such that the numbers of grid cells in these marginal strata are equal. This can be done using the quantiles corresponding to evenly spaced cumulative probabilities as stratum breaks. For instance, for five marginal strata we use the quantiles corresponding to the cumulative probabilities 0.2, 0.4, 0.6, and 0.8.

The objective function that is minimized is the weighted sum of three components. The first component is

$$O_1 = \sum_{p=1}^P \sum_{h=1}^H |n_{hp} - 1|, \quad (22)$$

Fig. 9 Spatial coverage sample (SC) and covariate space coverage (CSC) sample of 100 points from the Hunter Valley, NSW, Australia. In CSC topographic wetness index, normalized difference vegetation index and elevation are used as clustering variables.

Fig. 10 Conditioned Latin hypercube sample of 100 points from the Hunter Valley, NSW, Australia, using TWI, NDVI and elevation as covariates.

with P the number of covariates, H the number of marginal strata, n_{hp} the number of sampling units in marginal stratum h of covariate p , and $|\cdot|$ the absolute value operator. A second component quantifies how much the sample correlation matrix differs from the population correlation matrix. A third criterion is involved only when we have in addition to quantitative covariates one or more categorical ancillary variables. It quantifies how much the sample sizes in the categories deviate from proportional sample sizes.

With cLHS the marginal distributions of the covariates in the sample are close to these distributions in the population. This can be advantageous for mapping methods that do not rely on linear relations, for example machine learning techniques such as classification and regression trees (CART) and random forests. Fig. 10 shows a conditioned Latin hypercube sample of 100 points from the Hunter Valley (NSW, Australia), using the same three covariates as before in covariate space sampling. Of the 300 marginal strata there are 12 with no points, and as many strata with two points.

Model-based sampling designs

In model-based sampling a model of the spatial variation of the study variable (geostatistical model) is used to design a sample. Samples are obtained by minimizing a criterion that is defined in terms of variances of prediction errors. An example is the mean kriging variance criterion, i.e. the average of the kriging variances over all nodes of a prediction grid.

Model-based sampling therefore requires prior knowledge of the model of spatial variation. Such a model must be specified and justified. Once this model is given the sample can be optimized.

Optimization of grid spacing

Given a prior geostatistical model, we can use it to optimize the spacing of a regular grid. The grid spacing is derived from a required level of accuracy of predictions for mapping. I assume that the map is constructed by kriging. A kriged prediction of the variable at an unobserved location is accompanied by a variance of the prediction error, referred to as the kriging variance. The required accuracy is a population parameter of this kriging variance, e.g. the population mean of the kriging variance or some quantile of the cumulative distribution function of the kriging variance.

Fig. 11 shows a semivariogram of the soil organic matter (SOM) concentration (in dag kg^{-1}) in the western part of the Amhara Region in Ethiopia. This semivariogram is estimated from a large convenience sample along roads.

The semivariogram is used to design a new sample, a square grid, for mapping SOM across West-Amhara. The legacy sample (convenience sample) is not used in mapping, just for estimating the semivariogram. The kriging variance is independent of the observations at the sampling points, therefore, it is not a problem that at the stage of designing a sample we do not yet have observations of the study variable. The semivariogram is used to predict a dummy variable, 'observed' at the nodes of a square grid with a given spacing, at a simple random sample of 1000 points. The median (P50), 80th percentile (P80) and 95th percentile (P95) of the 1000 kriging variances is computed. This is repeated for a series of grid spacings. Fig. 12 shows the result; it shows that the tolerable grid spacing for a median kriging variance of 0.85 is about 11.7 km. For P80 not to exceed 0.85 the spacing is reduced to 9.4 km, and for the P95 this is further reduced to 7.1 km.

Fig. 11 Sample semivariogram and fitted spherical model of the SOM concentration, estimated from legacy data in West-Amahara of Ethiopia.

Fig. 12 Sample semivariogram and fitted spherical model of the SOM concentration, estimated from legacy data in West-Amahara of Ethiopia.

The same procedure can be used to optimize the grid spacing for kriging with external drift (KED), i.e. kriging with a geostatistical model in which the mean is a linear function of one or more covariates.

Optimization of sampling pattern

Once we have determined the tolerable grid spacing, s , we can compute the number of grid points by A/s^2 . But why should we sample on a regular grid? An irregular pattern of a sample of the same size may yield a more accurate map. A first option is to compute a spatial coverage sample, using k -means to optimize the sampling pattern as shown before. The alternative is to optimize the sampling pattern using, as before, the mean or some quantile of the kriging variance as a minimization criterion. For optimization we need some random search algorithm, for example, simulated annealing. Fig. 13 shows a model-based sample and a spatial coverage sample for an 80 ha site at the Cotton Research Farm in Uzbekistan to map soil salinity. The sampling patterns are quite similar.

Quick and dirty measurements of soil salinity can be obtained by an electromagnetic induction (EM) device. The EM measurements on transects covering the Cotton Research Farm were interpolated on a fine grid. The aim is now to design a sample at which the apparent electrical conductivity (EC) of the soil, a more accurate determination of soil salinity, will be measured. These

Fig. 13 Sampling pattern optimized for the mean variance of ordinary kriged predictions of $\ln \text{ECe}$ (Model-based sample) and spatial coverage sample (SCS) from the Cotton Research Farm.

Fig. 14 Optimized sampling pattern for kriging with external drift of $\ln \text{ECe}$ at the Cotton Research Farm, using $\ln \text{EM}$ as a covariate.

EC measurements can then be used together with the interpolated EM measurements to map soil salinity by KED. Fig. 14 shows the optimized sampling pattern for kriging with external drift (KED) of natural logarithms of soil salinity with the natural logarithms of EM as a covariate. The sampling pattern is less regular. Most striking is the preferential sampling of locations with either very small or very large values of $\ln \text{EM}$. The variance of the prediction error with KED can be decomposed into a component quantifying uncertainty about the mean and a component quantifying uncertainty about the interpolated residuals. The former variance component is reduced by selecting locations with extreme values of the covariate, the second variance component is reduced by spreading the locations throughout the farm. The optimized sampling pattern automatically balances both variance components.

Sampling for semivariogram estimation and mapping

There is extensive literature on sampling for estimating the semivariogram, see references in Brus (2022). In practice, we often cannot afford a reconnaissance sample for estimating the semivariogram, followed by a survey for mapping. It is more efficient to design a single sample that is used for both estimating the semivariogram and for kriging. Quite a few minimization criteria are proposed in the literature for designing such samples. All these methods require a prior geostatistical model and various assumptions must be made. A practical solution is to select a spatial coverage sample, and to supplement this sample with a sample of points at a short distance from the spatial coverage sample points. Fig. 15 shows a spatial coverage sample of 90 points supplemented by 10 points at 20 m from a randomly selected spatial coverage sample point, in a random direction.

Future research

The most important decision in soil sampling design is the choice between probability and non-probability sampling. It determines the types of statistical inference that are feasible. With probability sampling all three types of inference, design-based, model-assisted, and model-based, are feasible, whereas with non-probability sampling model-based inference is the only option.

Fig. 15 Spatial coverage sample of 90 points supplemented by 10 points at short distance (20 m) from randomly selected spatial coverage point.

For estimating (sub)population parameters probability sampling is recommended, whenever feasible. Extensive literature is available on how the accuracy of estimated (sub)population parameters can be increased by using a linear or non-linear model, relating the study variable to ancillary variables, in model-assisted estimation. However, publications on how spatial dependency of the study variable or the residuals of a linear or non-linear model can be exploited in model-assisted estimation are still scarce. I have seen papers in which a spline model is used to model spatial dependency (see references in Brus (2021)), but my experience is that this strongly underestimates the variance of the estimated population mean.

For mapping through prediction at points model-based inference is the natural choice. Also for this aim I recommend probability sampling whenever feasible, using a sampling design with equal inclusion probability for all units. Equal inclusion probabilities are important because in model-based inference these probabilities are not accounted for. When units are selected with unequal inclusion probabilities this may yield strongly biased predictions.

More research is needed into efficient probability or non-probability sampling designs for mapping with machine learning techniques such as random forest.

Abstract

Based on existing standards, this chapter describes validated and recommended methods for the handling of soil samples (i) in the field (optimal sampling conditions, choice of a sampling zone, usual sampling procedures for collecting and conditioning composite samples of humus and organo–mineral, samples from the horizons of a soil pit, samples to determine bulk density, water holding capacity and coarse fragments content), (ii) from the field to the laboratory (recommendations for the transport of soil samples) and (iii) in the laboratory (reception and registration of soil samples, soil preparation for chemical analysis, sending for analysis and archiving).

Key points

- Optimal soil sampling conditions and choice of a sampling zone
- Usual methods for collecting and handling of soil samples in the field
- Recommendations for the transport of soil samples from the field to the laboratory
- Procedures for reception, registration, preparation, sending for analysis and archiving of soil samples in the laboratory

Introduction

Soil properties are highly variable in space and time. Consequently, studying soil characteristics or evolution through analytical measurements requires the use of rigorous sampling and sample handling procedures, in order to have reliable results with low uncertainty. In particular for large inventories entailing numerous field operators or for monitoring purposes featuring repeated sampling over decades, it is crucial to apply routine protocols for reliability, replicability and avoidance of bias throughout the sampling – preparation – analysis – archiving chain. Beyond these two examples of application, these recommendations are valuable overall for every soil study involving soil samples.

Here, we present general procedures to sample, handle and transport, prepare and archive different types of soil samples, according to the elements needed to be analyzed. The following sample protocols are used by the French Soil Quality Monitoring Network (“Réseau de mesures de la qualité des sols,” RMQS, Jolivet et al., 2022) and by the European Soil Samples Conservatory (Conservatoire européen des échantillons de sols, CEES, INRAE Orléans, France). All these protocols follow or are adapted from ISO the International Organization for Standardization or NF AFNOR French standards.

In the field

Optimal sampling conditions

The following instructions are adapted from [ISO 18400-102 \(2017\)](#). The quality of the observations and samples depends mainly on soil humidity and cultural constraints. For instance, when collecting several sets of soil samples by auger at different depths, it is essential to minimize the risk of mixing the layers collected to avoid any risk of cross-contamination between samples. Similarly, the quality of the bulk density measurements used to calculate element stocks in the soil is subject to the conditions under which volumetric samples are taken. Therefore, these samples must be taken in compliance with climatic (soil moisture content) and cultural (physical condition of the soil) constraints.

Climatic conditions and soil humidity

The consideration of climatic conditions takes priority over any other criterion in the choice of the sampling period, even if this interferes with organizational constraints. The ideal conditions for description and sampling are met when the soil moisture is close to field capacity (drained soil). It is thus advised not to sample when the soil is too dry or too wet. For long-term soil monitoring, it is important to keep as close as possible to similar sampling conditions to be able to compare samples from different sampling campaigns. Sampling during periods of drought or excessive moisture should be avoided, not only because of the physical difficulty of taking quality samples, but also for reasons of observational accuracy.

Dry conditions should be avoided because they make auger sampling difficult, especially in stony or sandy soils. The upper part of a dry soil sample is often truncated, which can have consequences for the validity of the contents measured. Similarly, the lower layer of the soil cannot be reached or is insufficiently sampled. Finally, the risk of cross-contamination of samples between two sampling layers increases greatly when the soil is too dry, as surface soil can easily fall into the hole.

Soil that is too dry makes it difficult nor impossible to take the volumetric samples used for bulk density determination. This is particularly true for sandy soils, where samples are too fragile, and for clay soils, where compactness may bias the sampling. A soil that is too dry is also more difficult to describe, as the structure, colors (and therefore the detection of mottles, for example) are poorly expressed.

When the soils are too wet, in addition to the damage to vegetation and soil compaction that can be caused by trampling in excessively wet conditions, waterlogging considerably hinders the quality of sampling, especially that by augering. This is particularly true when the soil is clayey, as the samples are sticky and more difficult to extract from the auger.

In waterlogged soils, observations on the profile are more difficult (some structures are closed, for example) and it is more difficult to carry out volumetric sampling with precision, in particular in the deep layers of the soil, which may be saturated by the presence of a temporary water table.

Cultural constraints

In cultivated soils, taking samples from blown, recently plowed, stubble or deep plowed soil should be avoided to circumvent any bias related to agricultural work, not only because of the difficulty of taking quality samples, but also for reasons of observational accuracy. The ideal conditions for description and sampling are met when the tilled layer is homogenous in terms of structure and compaction, for instance after seedbed preparation or after a few weeks of natural settling. These precautions are paramount for the collection of surface composites and for the determination of soil bulk density in volumetric samples. The sampling dates must therefore consider the calendar of cultivation operations, obtained from the farmers during the survey and revalidated during contact with the farmer or manager before the operation.

Information on the sampling conditions, in particular the water status of the soil, weather conditions, vegetation cover, land use, must always be noted on the sampling report or field notes (see below).

Sampling zones

The following instructions are adapted from those in NF X31-100 (2020). The choice of sampling site depends on the objectives, however, in general a site should be located in a homogeneous area in terms of occupation or management practices. Some areas should be avoided as follows:

- agricultural pounds,
- woodland edges,
- areas that straddle plots that have been consolidated or are under different crops,
- the edges of roads or stony paths, old roads that have been reconfigured (observable in particular by the presence of a slight eminence or of allochthonous pebbles),
- the immediate banks of streams and ditches,
- coal-mining rounds or former fireplaces,
- ancient human settlements (signature from the surface by shards of flint, shards, bricks, various debris, charcoal and/or black color on an abnormal thickness),
- the immediate proximity of buildings,
- small localized bumps or depressions,
- illegal dumpsites, scrap metal dumpsites.

Avoidance of artificial contamination of samples

Before any sampling, it is necessary to ensure that the equipment used (augers, knives, sampling shovels, buckets, mixing containers, etc.) does not cause any interference (pollution or loss) with the soil properties being analyzed. Thus, according to the type of analysis, equipment made of different material should be used to avoid contamination of the samples by the material, tools and containers.

In general, plastics bags, plastic trays and stainless-steel tools are used, but caution should be exercised for samples taken for metal trace element measurements, DNA analyses and determination of organic compounds:

- For samples to determine metal trace elements, equipment made of copper, brass, galvanized or chromium-plated steel or covered with paint should be avoided. Plastic or raw steel tools should be given preference. Plastic buckets and tubs (polyethylene or polypropylene) that can be carefully washed after conditioning with HCl (hydrochloric acid) should be used for sampling.
- For DNA analyses the samples must not be handled with bare hands to avoid any human DNA contamination of the samples: single-use latex gloves must be used to handle the samples.
- For the analysis of organic compounds, plastic containers or plastic bags should be avoided (ISO 18400-105, 2017) as they may adsorb contaminants.

In addition, to avoid any risk of direct or cross-contamination between different samples all sampling tools (e.g. auger, knives) and containers (e.g. trays, buckets) must be washed thoroughly with tap water then rinsed with demineralized water and then carefully dried with paper towels. This must be done systematically between two samples.

Sampling procedures

Collection of organo-mineral or mineral samples by augering

Individual sample

If the protocol does not include sampling an undisturbed soil core with a soil sampling ring or a mechanical soil coring kit, the organo-mineral and mineral samples are collected using a helical soil auger (for example EDELMAN auger). A soil auger of 7 cm in diameter is generally used to provide enough material for later use. The handle of the auger should be graduated to check the sampling depth. This can be done by attaching a piece of colored tape every 10 cm along the handle.

Sampling starts at the surface of the soil in bare soil. In the presence of dense vegetation, e.g., under grassland, plants should be removed with a knife before augering to avoid the incorporation of vegetation debris into the sample.

Systematically remove the edges of the core and its 'tip' with a knife. This precaution is imperative for two reasons: (1) to avoid any risk of cross-contamination between horizons when the core sample is in contact with the augerhole wall and (2) to collect a constant volume of soil if the objective is to form an unbiased composite sample, by mixing the different element samples in equal parts. If the soil samples are for DNA analyses, they must be handled using single-use latex gloves (see above) or with a clean knife to level the auger and place the sample in the collection bucket.

If the samples needs to be taken in several stages to reach the defined depth, the upper part of each core (about 10 cm) should also be removed. A helical auger with a diameter of 7 cm allows the removal of only 20 cm of soil when starting from the soil surface. After that, this type of auger only allows an advance of 10 cm at each 'auger turn.' The first 10 cm of the upper part of the core, which corresponds to soil that falls to the bottom of the auger hole when removing and reintroducing the auger, must be removed at each 'auger turn.' The auger should not be filled to excess. It is better to carry out the sampling in several stages to avoid the risk of biasing the sampling depth or of getting the auger stuck in the hole. Each sample is bagged separately.

Composite sample

To provide a representative sample of a plot, for instance for agronomic analysis or monitoring purposes, several individual samples are collected according to a specific sampling design, then composited. The principle of producing a composite sample is to homogenize by mixing equal parts of the material from a series of samples for each soil layer taken from the sampling area. In this case, the procedure for collecting each individual sample for the composite is repeated as many times as needed.

For monitoring purposes, two buckets per operator are used to collect each composite sample: the sample material intended for the composite sample is placed in a first bucket, which was previously cleaned (see above). The sample waste is placed in a second bucket and then eliminated to avoid contamination of the sampling surface. To prevent cross-contamination between soil layers, the buckets used for sampling are carefully cleaned.

After the sampling, the auger holes should be resealed with surface earth to prevent injury to animals and fauna (cattle with broken legs, insect and small animals falling into the auger holes).

Depending on the monitoring methods of analysis and the archiving objectives, a minimum amount of sample might be necessary. In stony or shallow soils (< 15 cm, Fig. 1, case 1), it may be difficult to collect a sufficient amount of sample in one pass. In this case, two or more samples can be taken from each plot to ensure that enough material is collected to make up the surface composite sample. The use of a smaller diameter auger (4 cm) is possible if it makes sampling easier, but in that case, the samples should be multiplied to obtain a sufficient quantity of composite sample. Caution: in the event of an occasional blockage of the auger, the upper part of the sample during a second auger coring should be discarded to avoid over-sampling the upper part of the soil profile (Fig. 1, case 2).

The soil samples are then taken from the collection buckets and placed onto a tray that has been previously cleaned. The soil is carefully swabbed using single-use latex gloves, then mixed thoroughly to form a composite sample. Depending on the amount of sample required, the whole of each composite sample can be bagged entirely, quartered, or bagged separately.

Collecting samples of humus horizons

In forest or old field soils, humus horizons can be sampled before collecting organo–mineral horizons (Fig. 2). After the litter (Oi layer) is removed or collected, in addition a sharp cylinder is pushed vertically to a depth sufficient to pass through all the O horizons (Oe + Oa layers), using a mallet if necessary. If the organic layer is thicker than the cylinder height, sampling can be done in two stages.

The cylinder is then carefully removed from the soil surface with a knife. The organic layer cut by the cylinder usually remains inside it. If not, the cylinder is removed and the previously cut organic layer is lifted out of the hole made by the cylinder. The mineral or organo–mineral fragments are then removed from the underlying horizon as needed. The Oe and Oa layers can be separated or kept as a whole. The average thickness of the whole sample or each horizon is measured and recorded in the sampling document if necessary.

The sample is placed in a plastic bag for individual analysis or in a bucket for compositing. In this case, the samples are gathered in a previously cleaned container (see above). Each sample is coarsely disaggregated and mixed carefully to form the composite. Single-use latex gloves should be used to take the samples and make up the composite sample to avoid any human DNA input.

Collecting samples of horizons from the soil profile of a soil pit

Before sampling, the pit wall should be cleaned thoroughly by working from top to bottom using a scraper (Berthelet trowel) or a knife, for example. Then, with a small shovel or a knife, the samples should be taken from the bottom upwards to avoid the step of cleaning the pit wall in between sampling. If possible, sample within each horizon (organic, organo–mineral and mineral), across the entire width of the profile wall to obtain a representative sample of the horizon.

Collecting volumetric samples for bulk density determination from the soil profile

Volumetric samples should be taken under moist soil conditions close to field capacity and in stabilized soil, i.e., not recently worked (plowed, stubble, subsoiled) (see above).

Fig. 1 Sampling of composite samples in stony and shallow soils (Jolivet et al., 2022).

Fig. 2 The different steps to take a sample of an holorganic horizon (Jolivet et al. 2022).

Three methods can be used: cylinder, water, and sand. Depending on the constraints of the soil (coarse particle load, root density, slope), it is up to the sampler to choose the most suitable method. The method used can be different between two soil layers or horizons, but only one method should be used within a soil layer or horizon.

The cylinder method (core method)

The cylinder method is suitable for soils with little or no gravel, stones or roots. It is described precisely in the standard NF EN ISO 11272 (ISO 11272, 2017). The steps of the cylinder method are described in Fig. 3.

Note: vertical sinking of the cylinder is strongly recommended. It is mandatory in surface horizons, but horizontal sinking of cylinders is also possible at depth.

The water method

This is an excavation method adapted to gravelly or rocky soils, or in the presence of a high root density. It corresponds to an adaptation of the method described in standards NF X 31-503 (NF X31-503, 1992) and NF EN ISO 11272 (ISO 11272, 2017). The methodological modifications concern the principle, the material and the field procedure. Everything related to the definitions, the expression of the results and the laboratory procedures (material and operating mode) is in accordance with the standard mentioned.

In the field, after the soil has been levelled, the procedure consists of creating a cavity, collecting all the soil to measure its mass and water content in the laboratory, placing a watertight plastic bag in the cavity and then filling the bag with water to determine the volume of the cavity. The steps of the water method are described in Fig. 4.

The main difficulty with this method is to obtain a surface that is sufficiently flat to allow the water level to be adjusted precisely to the ground surface. Therefore, it is not suitable for small volumes. On the other hand, it should be used when the cylinder method is difficult to use i.e., in the presence of gravel or stones, in the presence of roots, or in very clayey horizons. The stonier is the soil and the larger the pebbles (stones or boulders), the larger the volume of the cavity should be to improve the accuracy of the measurement: a volume close to 1500 cm³ is recommended.

Tip

A second sampling and measurement can be conducted using the first cavity made. The cavity can be deepened again, and the extracted soil collected, and the volume can be measured over the entire cavity. The volume of the second sampling will be deducted

1. The measurement can be carried out on the surface of the soil or in the deep horizons, working on the wall of a pit cut into a step. Prepare a horizontal surface using a trowel or scraper.		
2. Push in the cylinder vertically. Use a sharp cylinder and, if necessary, one or two mallets to drive it in.		
3. Gently remove the cylinder with a knife and a spatula or trowel.		
4. Gently flatten the two ends of the cylinder with a knife, using a plate on which to place the sample.		
5. Empty the cylinder into the sampling bag.		
6. Measure the depths of the sample (top and bottom) and record them on the sample bag and on the sampling report.		

Fig. 3 Steps of the cylinder method (Jolivet et al., 2022).

1. The measurement can be carried out on the surface of the soil or in the deep horizons, working on the wall of a pit cut into a step. Prepare a horizontal surface using a trowel or scraper. It must be perfectly flat (checked with the level), using the knife and the scraper, before digging the cavity.	
2. Place the template (metal or plastic) on the floor and secure it with nails. Check the flatness with the level.	
3. Dig a cavity, collecting all the soil extracted in the sampling bag, without losses (use the brush to collect any losses that have fallen onto the template and any small aggregates remaining at the bottom of the cavity). Depending on the condition of the soil, dig with a knife, spoon or ladle. The diameter of the cavity should correspond to the template and the depth of the cavity should be adjusted according to the thickness of the horizon. Be sure to take a volume of between 1,000 and 1,500 cm³. The shape of the cavity is not important, but its edges should be as regular as possible: avoid indentations and outcrops of sharp or pointed coarse elements that could puncture the bag used to measure the cavity volume.	
4. Place the plastic bag in the cavity and press it against the walls. Fill the bag with water using the measuring cylinder until the surface level is reached. Ensure that the plastic bag adheres well to the walls of the cavity by correcting the adhesion with the spoon as you fill it. The volume of soil removed corresponds to the total volume of water poured into the cavity. Record the measured volume on the sampling bag and on the sampling report.	
5. Measure the depths of each sample (top and bottom) and record them on the sampling bag and on the sampling report.	

Fig. 4 Steps of the water method (excavation method) (Jolivet et al., 2022).

4. Place the plastic bag in the cavity and press it against the walls. Fill the cavity with calibrated sand using the measuring cylinder until the surface level is reached, pouring in the sand from a height of 5 cm to ensure an even distribution. Ensure that the plastic bag adheres well to the walls of the cavity by adjusting the adhesion as you fill it. The volume of soil collected is the total volume of sand poured into the cavity as measured with the measuring cylinder. Record the measured volume on the sampling bag and on the sampling report.

Fig. 5 Measuring the volume of the cavity with the calibrated sand (step 4 of the water method) (Jolivet et al., 2022).

from the total volume measured, minus the volume of the overlying sample measured. This method does not require a flat surface. It is only feasible for two successive repetitions, due to the difficulty of extracting soil beyond 20-cm depth and a 3 L bag of water.

The sand method

This method of excavation is suitable for gravelly or stony soils, or where there is a high density of roots. The sand method is described in the standards NF X31-503 (Measuring of bulk density - Sand method) (NF X31-503, 1992) and NF EN ISO 11272 (Determination of dry bulk density) (ISO 11272, 2017). It differs from the water method in that calibrated sand is used instead of water to measure the volume of the sampling cavity (step 4). All other steps of the method (steps 1, 2, 3 and 5) are identical. Its main advantage over the water method is that it does not require a perfectly flat surface to measure accurately the volume of the cavity. This is because the sand can be adjusted to the surface of a cavity where the edges are not level. To a certain degree, corresponding to the flow limit of the sand, the measurement can be carried out on sloping ground. The steps of the sand method are described on Fig. 4 (steps 1, 2 and 3) and on Fig. 5 (step 4).

The calibrated sand can be reused without time limit. Make sure it is completely dry before each new use. Dry it at 105 °C before the start of each year's campaign.

The clod method (special cases)

Measurement of the density of certain hardened horizons (iron pan, iron crust, etc.) requires the collection of small fragments of such horizons of a few cm³ and the use of the clod method (NF EN ISO 11272). Collect and condition the samples according to the method described in the following section (See above).

Collecting clod samples for the determination of available water content

This procedure describes how to take volumes of soil from an horizon while maintaining the soil's natural macroscopic structure to estimate the available water content of a profile horizon.

Sampling conditions

The ideal soil moisture conditions for sampling correspond to those of field capacity (See above). In the field, the structural state observed largely depends on the moisture content of the horizon. Thus, an horizon rich in swelling clays, which presents a massive aspect in a wet state, is likely to shrink and divide strongly in a dry period. Therefore, structure is a property that expresses itself more, or less, and also differently over time, according to seasonal cycles or according to meteorological events.

In addition to the indications given above, sampling in conditions that are too dry would not comply with the measurement methodology, which consists of extracting water from the soil at different potentials. Conversely, sampling under conditions that are too wet, apart from the fact that it would not allow the release of ideally expressed structural elements, would lead to settlement of the collected samples during their transport.

Operating procedure

Samples are taken from the top to the bottom of the profile. The steps of the clod method for the determination of available water content are described in Fig. 6.

When packing volumes of soil into the box, manually remove as much as possible from the areas smoothed by the tines of the digging fork or by the blade of the knife.

1. Remove a layer of soil of about 2 cm on the upper limit of the horizon with a knife.	
2. Use a toothed scraper to obtain a horizontal plane.	
3. Push the blade of a knife onto the lower limit of the horizon. 4. Crumble some soil from the horizon to be sampled into the bottom of the sample box (this crumbled soil layer will somewhat dampen the shaking when the samples are transported in the box).	
5. Carry out a superficial scraping or picking of the vertical surface of the horizon to be sampled to remove any particles that have fallen from the overlying horizon. This action also enables the identification of any rodent galleries or other small burrowing animals, as well as the presence of pebbles, rocks, buried residues, etc.	
6. Position the digging fork vertically, set back 20 cm from the wall of the profile, and drive it in ± 15 cm with a rubber mallet. Gently tilt the digging fork towards you while holding the volume(s) taken.	
7. Place volumes of soil of 10 cm size into the box, if the structure allows it.	
8. The box will then be filled up with smaller volumes (bearing in mind that the smallest size on which measurements are made in the laboratory is: ± 3 cm). Note: add only soil from the horizon and do not add paper, moss or any other material that can spoil or absorb soil moisture to fill up the box, as this may compromise the validity of the usable reservoir measurement.	

Fig. 6 Steps of the clod method for the determination of available water content (Jolivet et al., 2022).

Specific cases

The collection of coherent clods may be difficult to achieve in the following cases:

- Horizons with a structure that does not offer sufficient cohesion to collect clods (e.g., particulate structure).
- Horizons with a high proportion of gravel, pebbles and or stones.
- Horizons with high root density.
- Significant presence of plant debris.

In this case, take the horizon as it appears by simply removing stones and large roots. Fill a sample box as completely as possible. Another method (fine soil protocol) will be used in the laboratory to measure the water content at different water potentials.

Collecting samples to determine the coarse fraction contents of a soil horizon

The coarse content (stones, pebbles, gravels) is a key variable in the assessment of several soil characteristics such as organic carbon stocks or available water content. Because of the considerable spatial variability of the coarse fraction of the soil, measuring stoniness with sufficiently low uncertainty requires the collection of a large amount of soil, especially in the presence of pebbles and stones.

Sampling will be facilitated if soil moisture conditions are close to those of field capacity. Sampling is generally made from a soil pit. The pit should be wide and deep enough to collect a sufficient quantity of samples to be representative of each horizon in the profile. Because of the considerable soil disturbance associated with taking these samples, they should be taken last among the different kinds of sampling of the profile.

Sampling is started from the surface. On the first horizon, a spade or digging fork is used to mark out the area to be sampled. Shovelfuls of material from the horizon are then poured into the rubble bag. After weighing the sample on the scale, the mass is noted. Between two samples, avoid mixing horizons by neatly clearing the underlying horizon. After the surface sampling, a roughly flat area should be marked out again from the upper part of the underlying horizon. Then, the procedure is repeated as for the previous horizon.

It has to be noted that the sample should not be taken during the digging of the pit. It should be carried out as described above according to the horizons described, and without sorting or discarding coarse particles to avoid bias in the determination of gravel, pebbles, stones and blocks content. Woven rubble bags can double up on the sampling bags because they are more durable.

Sampling report, field notes

The sampling report or field notes are a critical document that links the samples to the laboratory and beyond. The set of field data and their presentation in a readable and understandable form in the sampling report is an essential prerequisite for understanding the laboratory results and their presentation and interpretation in general (ISO 18400-107, 2017). The report is completed at the end of the sampling and should contain information about the sampling conditions and any deviations from the sampling plan. These aspects should include effects on the samples and on the samplers, on the observations and field measurements, any instructions for testing and analysis, comments on sources of uncertainty, comments on accuracy, fidelity and variability. More explicitly, the report should include:

- sampler names, date and purpose of sampling,
- general information about the site and its environment: weather, land use and current practices, stage of cultivation, tillage, surface condition, indications of any soil disturbance, type of soil, how to access the site, coordinates of the site. . .
- the list and details of the samples collected: origin (surface or profile), type of samples, (individual, composite, horizon), sampling depth, sampling method, number of bags or containers. . .
- any relevant comment (e.g. difficulties when sampling).

For profile samples, the sampling report may be supplemented by the coordinates of the pit, a drawing of the profile description and sample locations for a better understanding.

Conditioning of samples

Soil samples may be subject to changes between sampling and testing as a result of physical processes (for instance variation in moisture content or change in structure for samples featuring thixotropic behavior), and chemical (for instance evaporation or precipitation of volatile substances, reactions with the sample container) and biological changes (for instance organic compounds degradation due to biological activity). The extent of these changes depends on the characteristics of the sample, its temperature, its exposure to light, the nature of the container in which it is placed and the nature of the compounds to be analyzed, the time between sampling and analysis, the conditions to which it is subjected and the seasonal conditions. The significance of these changes and the prescription of the packaging process, storage, transport and delivery should be considered so that samples are still representative when delivered to the laboratory (ISO 18400-105, 2017).

Soil samples are usually packaged in collection bags, annotated with their content information. All this information is repeated on a label attached to the rubber band used to tie the bag. The clod samples are packed in plastic boxes (more details below). The samples for the coarse fraction measurements are packaged in large specific bags.

After collection and before dispatch, the samples should be stored at a temperature close to that of the sampling, i.e., a sample taken in winter should not be stored near a radiator in the office and conversely, a sample taken in summer under high temperatures should not be stored in a refrigerator or left in a vehicle in direct sunlight but in a temperate place. A rapid dispatch of samples is advised. They should not be stored in the refrigerator, except for the clods. The plastic boxes containing the clod samples are best kept in a cold room at 4 °C, or, failing that, in a cool room (to limit biological activity and condensation) and in the packaging intended for their dispatch.

To keep the integrity of the sample during transport the following tips are useful during bagging and packing of the samples:

- The air from the sample bags should be emptied, to prevent them from bursting.
- The sample bag should not be overloaded, for example, it should be filled at a maximum of 2/3 of its capacity.
- The sample bag should be put upright in the cardboard boxes.
- It is important to check that the rubber bands are in place and properly tightened.
- The gaps in the cardboard boxes should be stuffed, for example with newspaper to prevent bags from moving in the cardboard boxes.
- The plastic boxes used to pack the clods should be checked to ensure they are closed, and then taped up if necessary.

For clod samples, there are several precautions to take for their packing:

- Make sure that the lid is correctly positioned on the plastic box and that the box is tightly closed all around the box and lid contact.
- Mark on the wide adhesive tapes, affixed on the side and lid of the box, the references of the horizon regarding the following three items: Name of the site/Upper and lower depth of the horizon/Date of sampling.
- Place the plastic box in a specific cardboard box with foam inserts to prevent the plastic box from breaking.

To dispatch the samples use robust packages dedicated to heavy loads, not too large; for example double wall cardboard boxes, reinforced with tape if needed. They should be filled to a maximum of 20 kg each to facilitate the handling and respect the heavy goods handling regulations. Empty spaces in the packages should be avoided, or stuffed. Careful handling of clod and or core samples during transport is essential if samples feature thixotropic behavior (thixotropic clays or soil samples with andic properties). In this case, shaking or shearing force should be avoided.

From the field to the laboratory

The instructions below are adapted from the ISO 18400-105 (2017).

After the field, the samples should be delivered to the laboratories as soon as possible. This could be done by the field team itself or the sample could be sent by a courier. In this case, a delivery service in less than 24 h is highly recommended.

If samples are intended for routine physicochemical analysis, transport at room temperature is sufficient. For measuring organic compounds, refrigerated transport at 4 ± 2 °C is advised (ISO 18400-105, 2017) to avoid microbial activity after sampling that could alter the content of the substances to be measured.

After reception by the laboratory, the samples should be stored in a cold room (4 ± 2 °C) to minimize sample perturbations if the measurements require fresh soil (for instance for biological analysis like microbial activity measurement or DNA extraction, or for chemical analysis on specific soils like Andosols) or before drying and preparation for routine analysis, as described in the next section.

In the laboratory

The work in the laboratory includes different steps according to the sample characteristics. It always starts with the reception and registration of the samples. Then, it may include the steps of weighing, drying, sub-setting and preparation to provide a laboratory sample designed for soil analyses and lastly, archiving if required. At each step, quality assurance actions are performed to avoid any cross contamination or bias. Moreover, the analytical laboratory keeps residual samples for some time after the analysis to check the result and redo the analysis if a result is uncertain.

Reception and registration of the samples

On reception, all the samples must be checked for physical integrity, identified according to the specifications and registered in a database. In case of an uncertainty or the detection of an anomaly in a sample, it should be identified as non-compliant and put on hold until a decision is made (kept or discarded).

Each sample is assigned with a unique number to allow its identification and origin, e.g. the geographic coordinates, the date of sampling, the samplers' usernames. Each action made on a sample is also registered in order to trace the sample's life cycle. A barcode linked to the number can be used to identify a sample in the laboratory, in the archive, or at other laboratories where it is being analyzed.

Soil preparation for chemical analysis

Soil preparation is a crucial step before laboratory analyses. This step encompasses several actions that should be registered in a database. Subdivision or creation of a sub-sample should also be registered through affiliation. The samples coming from the field are the 'parents' and the created sub-samples are the 'children.' This is useful to know if an analyzed sample has been sent to the analytical laboratory in a 'raw' state (coming directly from the field) or if it has been prepared or handled beforehand in the laboratory by, for example, sub-setting (with a sample splitter such as a quartering tray).

Avoiding any contamination and ensuring traceability of the sample

Depending on the properties to be analyzed, we refer to the following standards for handling the samples:

- For metal trace elements measurements: [X31-150 \(1984\)](#)
- For physicochemical measurements: [ISO 11464 \(2006\)](#)
- For organic compounds measurements: [ISO 14507 \(2003\)](#)

In the laboratory, it is essential to follow some procedures to avoid any contamination of the samples. Tools, containers and laboratory benches are carefully cleaned between each sample preparation.

In general, cleaning materials and products are non-abrasive sponges, clean tap water, demineralized water, wipes, ultrasound baths, compressed air guns. Buckets and sample bottles are blown with compressed air. Drying and quartering trays, tweezers, foil trays, beakers and sieve receiving pans are cleaned with a non-abrasive sponge and clean tap water. They are then rinsed with demineralized water, dried, and blown with compressed air. Sieves, mortars, pestles and spoons are, in addition, put in an ultrasound bath between cleaning with clean tap water and rinsing with demineralized water.

The laboratory benches are cleaned with clean tap water and non-abrasive sponges and then wiped. The laboratory and its equipment are also cleaned once a week: vacuum-cleaning and floor mopping, cleaning of the laboratory equipment, e.g. ultrasound baths, weighing balances. When handling samples, the operator must always wear gloves to avoid artificial contamination of the samples.

To ensure traceability of the samples, all the procedures they undergo are registered in a database in which each sample is linked to a soil profile or sampling site (see above).

Weighing

Samples are weighed ([Fig. 7](#)) for several purposes. As a control procedure to know how much sample is available, and to be able to detect any loss during the laboratory process. Weighing is also used to check if soil moisture was close to field capacity during the sampling by weighing the samples before and after air drying. Samples can also be weighed according to the procedure required for future analysis, for example if they are aimed at bulk density measurements.

Fig. 7 Weighing of a soil sample.

Fig. 8 Soil samples drying at the European Soil Samples Conservatory.

Drying

During drying of the samples, care must be taken to keep the integrity of the sample and avoid any contamination or physico-chemical changes. The samples, stored in the cold room from their reception, are placed in clean and dry trays on a clean laboratory bench (Fig. 8). The sample identification is noted on a label pasted on each tray: ID (database or program), origin (core, profile, composite), sampling depth, tray number/total tray number. With latex gloves on, the sample is spread and mixed in the labelled tray. Each sample is divided to a sufficient number of trays to allow rapid drying. Clods are reduced to small aggregates before spreading them as a layer no thicker than 20–25 mm in each tray. Empty sampling bags and labels are then thrown away. New latex gloves are to be used between each new sample preparation.

Trays containing the samples are stored in a drying room at a controlled temperature of about 30–40 °C. Drying is over when the aggregates are dry inside and outside. The drying time is a minimum of 10 days and lasts until a constant weight is reached.

Laboratory sample preparation

The purpose of sample preparation is to ensure a representative laboratory sample of fine earth (<2 mm particle size) for soil analysis. It involves two steps: crumbling and sieving the dried sample.

Crumbling

This consists of breaking aggregates and separating the coarse fraction from the fine earth using a porcelain mortar and a pestle. Clods are ground manually without crushing the coarse fraction (e.g. gravels and stones). Care must be taken with fragile materials such as pieces of limestone or concretions that should not be crushed. If the soil is fresh, this step of crumbling can be done by hand.

Sieving

The loosened earth is then hand-sieved using a 2-mm mesh sieve to obtain the fine earth fraction (Fig. 9). Coarse particles and roots, corresponding to the residue on the top sieve, are removed using tweezers. Sieving is completed when the coarse particles are clean. The efficiency of the sieving can be judged by checking the color or face of the coarse fraction. Depending on the programs, the coarse fraction is weighed and then either eliminated or archived for further studies.

Sample sub-setting—Quartering

The protocols for quartering are adapted from ISO standards (ISO 11464, 2006; ISO 23909, 2008; NF X31-100, 2020).

Fig. 9 Sieving is a step of soil sample preparation.

The objective is to prepare an aliquot of a representative soil sample in a sufficient quantity from a soil sample. The quartering can be done for two kinds of samples:

- The diagonal method for a large sample and or containing coarse elements or a raw sample (with aggregates).
- The quartering method can be used for any sample, but it is particularly adapted for small samples (if there is only one drying tray or fine earth material).

The diagonal method (Fig. 10)

The raw sample is spread over one or several trays. After the sample has been homogenized by mixing with a scoop, similar quantities are then taken from the whole thickness of the spread sample of each tray with a scoop along the tray's diagonal. If the quantity obtained is not enough, the remaining sample is thoroughly mixed and sampling of each tray is done along the opposite diagonal. In contrast if the sample is too large, it is re-homogenized and reduced using the diagonal method until the required quantity of samples is obtained.

The quartering method (Fig. 11)

The sample, previously homogenized, is spread like a flat pie on a flat surface or in a clean and dry plastic tray. Then, it is divided into four equivalent quarters by tracing two perpendicular axes in the pie with a knife or any other appropriate tool. Two opposite quarters are excluded and the remaining two are carefully mixed. The earth is again divided into 4 quarters. This time, the two opposite quarters excluded are those in the diagonal perpendicular to one of the two previously excluded quarters. This procedure is repeated until a sufficient quantity of sample is obtained. These actions are recorded in the database according to the program.

Preparation of samples from organic horizons

The preparation of organic horizons samples is similar to that of organo-mineral horizons (see above). The samples are weighed, then spread out in thin layers in trays for air drying for 2 to 5 days, until a constant mass is reached. Once dried, the rock fragments (stones and gravels) and living roots, mosses and other living plant material, are manually removed if present in the sample. Dead wood fragments and roots must not be removed from the sample as they are part of the organic horizon. Depending on the programs, the coarse fraction is weighed and then either eliminated or archived for further studies.

The remaining material is then ground to obtain fine organic material ($< 1 \text{ mm}$). This may be done using either a blade or bead mill provided that no contamination from the instrument can be guaranteed. An aliquot of a representative soil sample is extracted according to the diagonal or quartering method, with respect to the quantity of ground sample available and to the quantity of subsample required for soil analysis. The blade mill is cleaned between two samples. The electrical parts are blown with compressed air. The sieve and the receiving bucket are cleaned with non-abrasive sponge and tap water, then rinsed with demineralized water, wiped and blown with compressed air.

Sending for analyses and archiving

Sending laboratory samples for analyses

If samples are prepared at a location different from the one of the laboratory analyses, once prepared they will be sent for analysis in the laboratory. Aliquots aimed at laboratory measurements are typically put in sample bottles (made in PP polypropylene or PEHD

Take a sample along the diagonal of each of n trays, put the n samples in a new clean and dry tray.

Carefully mix all the takings so as to constitute a homogeneous sub-sample.

If the obtained quantity is not sufficient, homogenize again the earth of trays 1 to n and proceed again but taking the opposite diagonal. Begin again until the requested amount is reached.

Fig. 10 the diagonal method is used for the quartering of large soil samples, samples containing coarse elements or raw samples with aggregates.

Fig. 11 Description of the quartering method for fine earth sample preparation for bulk density measurements.

polyethylene) (60, 100, 250 or 300 g) or Kraft paper bags with a plastic coating inside (Fig. 12). Before packing them, the samples will be checked to ensure that they are correctly closed and labelled. Type, material and transport are adapted according to the required analyses. Care should be taken to wedge the sample bottles in place, especially if they are made of glass, for example by stuffing the empty spaces. In the package, the samples will be accompanied by a list of all the samples contained in the package and a letter. The correspondence between the list of samples and the package content should be checked before closing it. According to the program, a request will be made to the laboratory to return the remaining samples after analysis. When samples are returned there must be a list that contains the sample database references, so that the correspondence can be established in the laboratory.

Fig. 12 Examples of soil sample containers for sending aliquots for analytical measurement and for long-term storage.

It is convenient, if not necessary, for the analytical laboratory to have the same barcode reader system as the preparation laboratory to ensure traceability of the samples and to avoid any confusion with the samples analyzed.

Archiving

Short-term storage of raw or prepared soil samples is quite common in most laboratories, often for verifying analyses. Long-term storage or archiving has different aims for example (ISO 18512, 2007):

- To take a new aliquot of a sample to check a previous analysis or a change in the method of analysis.
- To be able to determine the initial state of a sample, for example, if a significant change or some pollution has been recorded later on the sampling site.
- To perform new kinds of measurements that did not exist at the time the sample was first analyzed, which can be decades before.
- To provide a representative collection of soil samples for further research studies.

Samples can be re-used if the archiving conditions do not change their properties. The following conditions are considered optimal to prevent evolution, either for raw or fine earth samples:

- Air-dried (30–40 °C) soil samples
- Stored in food grade plastic buckets (e.g. 8 L) or thermo-weldable bags of 1, 2 or 3 L capacity (Fig. 12).
- Hermetically closed and kept in the dark
- Constant climatic conditions of storage as 18 ± 2 °C and 50% humidity.

The use of sliding shelving is a good solution to save space in the archiving facility (Fig. 13). The use of barcodes and the registration of the samples in a database allows quick identification, location and recovery of the samples when needed.

Conclusion

Soil is now back on the political agenda: soil data will be needed more than ever to report on the success of policies. Even if remote sensing techniques are developing fast for assessing and monitoring soils, sampling still remains the first step needed to report on the soil's status. Based on existing standards, this chapter describes the validated and recommended methods for handling of soil samples in the field, during transport to the laboratory and in the laboratory. Despite the constant progress of on-board analytical methods that can be deployed in the field or the development of robots for soil sample preparation in the laboratories, the human hand remains fundamental for the moment to collect and prepare quality samples that ensure repeatable and reproducible samplings to detect any evolution of soil properties without bias. The use of standardized protocols is the prerequisite for comparing data from different countries. This will eventually lead to a globally harmonized soil quality monitoring network, to support and control the efficiency of public policies toward the protection of our soil heritage, soil functions and services rendered by soil.

Abstract

Digital soil morphometrics uses pedometric techniques in the morphological study of soil profiles. It combines tools and techniques for measuring and quantifying soil profile attributes and deriving continuous depth functions. Most soil profile attributes can be measured rapidly and quantitatively using proximal sensing techniques through image analysis methods, including soil color, soil structure, and coarse fragments. More objective and quantitative horizon delineation methods can be executed using cluster analysis of proximally sensed data, e.g., sourced from visible-near infrared and portable X-ray fluorescence spectroscopy, as well as digital images. Moreover, 1-D continuous depth functions and 2-D soil profile maps have been generated to visualize and quantify soil profile variations better. Advanced profile sampling schemes have been established to cover soil profile variation and reduce sampling effort. Digital soil morphometrics offers new quantitative and objective measures of soil profile attributes and their variability.

Key points

- Digital soil morphometrics uses proximal sensing technology for measuring and quantifying soil profile attributes.
- The tools and methods have been used to quantify soil profile attributes, including soil color, soil structure, soil horizons, and coarse fragments.
- Continuous depth functions have been developed to display the vertical distribution of soil properties.
- Soil profile maps have been generated using geostatistical methods or machine learning methods to quantify 2-D variation of soil profiles.
- Proximal sensing increased soil profile sampling density and efficiency, and advanced sampling schemes exist to investigate soil profile variation.

Introduction

Digital Soil Morphometrics was coined by Hartemink and Minasny (2014) as “the application of tools and techniques for measuring and quantifying soil profile attributes and deriving continuous depth functions”. It is a branch of quantitative pedology and investigates the quantification and variation of soil profile characteristics. Furthermore, digital soil morphometrics is extended from “soil morphology” by adding the “digital” and “metrics” parts to indicate the use of quantitative tools and methods to study morphological features of soil.

Soil morphological features have been primarily described in the field in excavated soil pits or trenches using a shovel, auger, knife, root cut, tape measure, water bottle, Munsell color book, chemicals such as Hydrochloric acid (HCl), clinometer, compass, GPS, and camera (Hartemink, 2015). Although the field description is equipped with official guidelines, such as from the *Soil Survey Manual* (Soil Science Division Staff, 2017) and *Field Book for Describing and Sampling Soils* (Schoeneberger et al., 2012), it requires

substantial pedological experience and may be subjective. Soil samples are collected from soil profiles for the analysis of physical, chemical, and biological properties in the laboratory. Because of its cost, however, only a few samples are collected to represent the whole soil profile, which may compromise the accuracy and lead to large sampling uncertainty. The increasing demand for data in decision making to support agricultural management and soil conservation and for environmental modeling has pushed forward the development of more rapid, quantitative, and objective tools and methods to obtain soil information.

Proximal soil sensing technology has been developed and adopted during the past two decades. It has improved the effectiveness of soil survey by providing rapid and reliable ways to estimate soil properties and reducing the effort and time to characterize field-scale variation with on-the-go instruments. Some hand-held proximal soil sensing tools advanced the characterization of soil profile features, as they capture the two-dimensional (2-D) soil profile variation in fine resolution with digital and hyperspectral cameras. Visible near-infrared (vis-NIR) and portable X-ray fluorescence (pXRF) spectroscopy can rapidly increase the sampling density of soil profiles. It increased observations to provide soil data that enhance the understanding of pedological and weathering processes. The high-spectral resolution data collected with proximal sensing tools have improved the objectivity of profile description of soil attributes and horizons. With the increasing accessibility of these tools to many research groups, it will become a routine method to complement soil profile description.

Measuring soil profile attributes

Soil color

Soil color is determined by mineral composition, element concentration, organic matter, and moisture content. It reflects soil properties and soil processes, and it is an important diagnostic feature for soil horizon delineation and soil classification. Soil color has been described on both dry and moist soil samples by comparing its color with the Munsell color chart. The Munsell color system describes a soil color using three attributes—hue, the basic color (e.g., 10YR, 5YR); value, the lightness ranging from 0 (black) to 10 (white); and chroma, the color intensity or saturation ranging from 0 (gray) to 12 (pure color). Soil Munsell color description is subjective, and its readings are affected by light conditions and human perception. The Munsell color chart provides discrete values which hinders its use for quantitative analysis. Therefore, other tools (e.g., digital camera, scanner, colorimeter, and spectrometer) and numeric color systems (e.g., RGB, CIE $L^*a^*b^*$, and HSV) are used to determine soil color. They are reviewed below.

The RGB color represents red (R), green (G), and blue (B), with values ranging from 0 to 255. The CIE (Commission on Illumination) $L^*a^*b^*$ color represents lightness (L^*) ranging from 0 to 100, and colorimetric values from red ($+a^*$) to green ($-a^*$) and yellow ($+b^*$) to blue ($-b^*$). The HSV color represents hue, saturation, and value (lightness). These color space models can be converted from each other by mathematical formulae with open-source software. In addition, soil numeric color systems can be converted from Munsell color or reflectance spectra in the visible range (400–700 nm). Digital cameras and cellphone cameras have been used on individual soil samples and soil profile walls to determine soil color. The RGB, CIE $L^*a^*b^*$, and HSV colors can be extracted from digital images using image analysis software (e.g., ImageJ) or computing software (e.g., R programming, Matlab). As cameras have different settings and the light conditions vary when taking photographs, soil color extracted from digital images should be calibrated using a standard color chart or standard spectrometer measurements to obtain colorimetrically accurate images. Calibration methods have been developed for both dry and moist soil conditions.

Soil colors determined by digital cameras or spectrometers have been used to predict soil properties directly related to soil colors, such as soil organic carbon (SOC), iron oxides, soil texture, and moisture content. Some mobile phone apps have been developed based on the relationship to estimate SOC from images rapidly. These relationships can be applied to predict soil properties from high-resolution soil profile images and to map the 2-D variation in soil profiles. Soil color varies between soil horizons, and therefore soil colors extracted from soil profile images can be used to differentiate horizons (Fig. 1). Other color contrast features, such as redoximorphic features, krotovinas, and rocks, have been identified and their shapes and distribution can be quantified using image analysis methods.

Soil structure

Soil structure describes the arrangement of soil particles and soil aggregates. Soil structure is an important physical property that influences water and nutrient flow, aeration to plants and microbes, and resistance to soil erosion and compaction, through which it affects plant growth. A strong soil structure can provide sufficient water, nutrients, and oxygen to support plant growth and enough space for roots to penetrate, while poor soil structure impedes root growth, water movement and drainage. Soil structure is described qualitatively in the field on the types (granular, blocky, prismatic, platy, for example), size (fine, medium, coarse), and grade (weak, moderate, strong). Likewise, describing soil structure is subjective, and a quantitative and objective method is needed for broader use.

Three-dimensional (3-D) laser scanners such as a multi-stripe laser triangulation (MLT) scanner can take 3-D objects at 360 degrees and build a 3-D structure for visualization and analysis. The surface area and volume of the 3-D object and its geometric parameters can be quantified using image analysis methods on the constructed 3-D images. This technique has been used on soil clods and soil aggregates to determine the volume and bulk density (Hirmas et al., 2013). The MLT scanner has been used to scan 2-D soil profile walls or soil monoliths with a rough surface to identify soil structure and macropores. The MLT-derived profile

Fig. 1 A sandy, mixed, frigid Entic Haplorthods, Rousseau series from Door County, WI, United States and derived RGB, CIE $L^*a^*b^*$, and HSV colors from the soil profile image.

image reveals structural units and scan gaps representing pore spaces between the structural units, which can be used to derive soil structure indices and quantify macropores (Eck et al., 2016). It can monitor the dynamics of macropores during the drying process and be used to evaluate tillage effects on soil structure.

Soil aggregate stability is an important indicator of soil structure that measures the ability of soil aggregates to resist disintegration when forces from water, wind, and tillage are applied. It can be evaluated using the slaking method which refers to the breakdown of a large, air-dry aggregate (>2–5 mm) into small aggregates (<0.25 mm) when it is immersed in water. A mobile phone app—Slakes, has been developed to measure the area changes over time after soil aggregates are dropped into a petri dish filled with water, which can be fitted into a model to calculate soil aggregate stability indicators (Fajardo and McBratney, 2019). This method has been used to evaluate the effects of tillage on soil aggregate stability in Vertisols (Flynn et al., 2020). It provides a rapid and quantitative measure of soil aggregate and soil structure for effective soil management practices.

Soil horizons and horizon boundaries

A soil profile contains layers often parallel to the soil surface called soil horizons. A soil horizon is the result of soil-forming processes and its physical, chemical, or biological properties differ from adjacent horizons. Soil horizons are identified in the field

by visible features, mainly soil color, texture, structure, rocks, and redoximorphic features. Genetic soil horizons are described by symbols, including capital letters representing master horizons, lowercase letters representing suffixes associated with specific soil characteristics within master horizons, and numbers representing subdivision of horizon suffixes or different parent materials. Soil classification systems use diagnostic horizons, such as epipedons and diagnostic subsurface horizons in USDA Soil Taxonomy, to define soil types. Some soil horizons with distinct color or texture features are easier to identify, such as a Bh horizon in Spodosols with brownish colors stemming from increased organic matter content and sesquioxides, Bt horizon in Alfisols with illuvial accumulation of silicate clay, whereas in some profiles where haploidization processes dominate so that soil horizons are not easily discernible. Additionally, field delineation of soil horizons is subjective and novel tools and mathematical methods have been explored and evaluated to identify soil horizons quantitatively and objectively.

The vis-NIR spectroscopy measures reflectance spectra of soil samples at 350–2500 nm which reflects amounts of organic matter, mineralogy, texture, and moisture. The pXRF spectroscopy measures the concentration of total major and minor elements in soil samples, such as Al, Si, Fe, Ca, Mg, Ti, and Zr, and the spectral response of pXRF at different energy levels can also be extracted and used for further analysis. The vis-NIR spectra and pXRF element data recorded on soil cores have been used in cluster analysis to identify spectrally homogeneous parts which are regarded as soil horizons (Fajardo et al., 2016). Cluster analysis can group objects with similar attributes and separate objects with different attributes using numerical methods. The soil samples with similar characteristics in the vis-NIR spectra and pXRF data are assumed to be from the same horizon, and the transition of different horizons can be identified by calculating a digital gradient, which is considered a horizon boundary. This method has been applied on one-dimensional vertical transects or soil cores.

The 2-D soil profile images contain soil color information which is a major attribute to identify soil horizons. The soil color image or predicted soil properties of the 2-D soil profile had been used in cluster analysis to identify homogeneous regions of soil color or other properties which are regarded as soil horizons (Zhang and Hartemink, 2019a). Soil horizons are often assumed to be homogeneous, but there is substantial within-horizon variation (Hartemink et al., 2020). Fuzzy cluster analysis is advantageous over hard clustering (e.g., *k*-means clustering). It shows the membership of the soil to a specific cluster, i.e., a soil horizon instead of rigorously assigning it to a specific cluster. An example of fuzzy clustering to delineate soil horizons and cluster membership maps is shown in Fig. 2. Delineating soil horizons on 2-D soil profile images is advantageous over 1-D soil cores because the lateral distribution of horizon boundaries can be delineated. Soil horizon boundaries are described on the basis of two characteristics: (1) distinctness indicating the thickness of the transition zones, and (2) boundary topography indicating the shapes or irregularity of the boundary (Schoeneberger et al., 2012). Quantitative methods to assess the horizon boundaries by calculating tortuosity, curvature, distinctness, and topography have been successfully applied on 2-D soil profile images (Zhang and Hartemink, 2019b).

Fig. 2 An example of fuzzy clustering analysis to delineate soil horizons in an Alfisol (fine-silty, over clayey, mixed, superactive, mesic Typic Hapludalfs, NewGlarus series). The membership maps refer to the membership values ranging from 0 to 1 in each cluster corresponding to each horizon. The confusion index map provides implications on horizon boundaries. Fig. 3 An example of an image analysis method for identifying coarse fragments in a soil profile image of a coarse-sandy, mixed, superactive, mesic Typic Aquic-Alluvic Primosols. Jiang ZD, Wang QB, Adhikari K, Brye KR, Sun ZX, Sun FJ and Owens PR (2020) A vertical profile imaging method for quantifying rock fragments in gravelly soil. *Catena* **193**: 104590.

The use of proximal sensing tools (e.g., vis-NIR and pXRF spectroscopy, digital cameras) with a clustering approach provides methods to identify quantitatively and objectively homogeneous regions as soil horizons on 1-D soil cores or 2-D soil profiles. Combined with pedological knowledge, it is a powerful tool to delineate and name soil horizons accurately. Soil horizons with more distinct color and textural features, mainly master horizons, are more accurately identified than less distinct horizons.

Coarse fragments

Coarse fragments, also known as rock fragments, refer to particles with a diameter greater than 2 mm. It is an essential attribute that affects soil physical and hydrological properties, soil and water management, plant growth, and soil carbon stock assessment. Coarse fragments are primarily quantified by percentage in weight or percentage in volume in the soil sample. The volume of coarse fragments is determined by the water displacement method, which measures the increase in volume when the rocks are placed in a fixed amount of water in a graduated cylinder. In addition, its size and shape (roundness—very angular, angular, subangular, subrounded, rounded, and well-rounded) are described. Quantifying coarse fragments is essential for soil water management and accurate assessment of SOC stocks, but it can be tedious in stony soils and destructive to soil profiles. Therefore, other efficient methods, such as image analysis, have been developed.

For single gravel fragments, the MLT scanner has been used to construct the gravel's 3-D structure, which can quantify the surface area, volume, and density of the gravel. For a single soil sample, digital images can be taken on the sieved and evenly spread coarse fragments and their content and shape parameters (circularity, aspect ratio, roundness, and solidity) can be quantified using image analysis. To reduce the effort and avoid destruction of the soil profile, image analysis methods have been used to quantify coarse fragments in soil profile images (Jiang et al., 2020)—see Fig. 3. An image segmentation method was used on HSV image colors to differentiate coarse fragments from soil materials, and this method accurately identified 84.9% of the coarse fragments. To construct 3-D structure from 2-D shapes of gravels, a stereology method has been developed to construct the 3-D geometry by fitting an ellipsoid that can estimate the volume of the coarse fragments (Jiang et al., 2021). It provides an efficient way to identify and quantify coarse fragments in soil profiles, increasing the accuracy of assessing SOC stocks in the soil profile.

Other soil properties

Proximal sensing tools have improved the efficiency of measuring other attributes in soil profiles. The pXRF spectroscopy has been used to measure total elements in vertical transects in soil profiles in the field, which reduced the time of chemical analysis in the laboratory. Dense scans of a 2-D soil profile wall characterizes lateral and vertical variations. The vis-NIR and mid-infrared (MIR) spectroscopy have been combined with statistical or machine learning models to predict soil properties (e.g., organic carbon, soil texture, moisture content, carbonates, salinity, pH, etc.). When the predictive models are developed using an existing representative of soils studied, the models can rapidly estimate soil profile attributes. This fulfills the need for collecting soil profile information rapidly to study soil processes or environmental modeling. Future work should focus on improving the spectral models' predictive ability on a wide variety of soil types and developing new tools and techniques to characterize soil profile attributes.

Soil profile variation

Soil depth functions

Soil profile variation occurs from the soil surface to the parent material. As described above, the vertical variation is usually split into homogeneous regions, called soil horizons, within which the soil properties are assumed to be homogeneous. With soil samples collected on a horizon basis and analyzed for soil properties, the vertical distribution of the properties is displayed in a segmented pattern. In many cases, soil properties vary continuously with depth, and such a distribution could be presented more suitably using the continuous depth function. Jenny (1941) stated that every soil property has its own specific depth function. Depth functions with mathematical equations have been developed for several soil properties.

The SOC content generally accumulates in the topsoil and the amounts decrease with depth. The vertical distribution of SOC has been modeled using an exponential decay function with parameters representing carbon content at the soil surface and decreasing rate (Eq. 1) (Minasny et al., 2006). Some soil properties have a peak distribution where the concentration is higher in the subsoil than that in the top or at greater depth. Two peak functions with specific parameters have been developed to model such distributions by Myers et al. (2011). Soil pH in some cultivated fields showed uniform distribution in the topsoil and at greater depth in the soil profile and a transition region (either increasing or decreasing) in between. Such a distribution has been modeled using a sigmoid function with parameters representing the soil pH of the topsoil and at depth and the transition rate (Eq. 2) (Zhang et al., 2017). In addition, the non-parametric equal-area quadratic spline function has been proposed, which has the most flexible shape to model any vertical distributions and the areas above and below the fitting spline in each sampled horizon are equal (Bishop et al., 1999). Some examples of the exponential decay function, peak function, and sigmoid function are shown in Fig. 4.

$$y = C_a e^{-kx} + C_b, \quad (1)$$

$$y = s + \frac{d-s}{1 + \left(\frac{x}{\alpha}\right)^{-k}}, \quad (2)$$

where C_a (kg m^{-3}) is the difference in SOC content between the soil surface and the bottom of the profile, C_b (kg m^{-3}) is the SOC content at the bottom of the profile, $C_a + C_b$ (kg m^{-3}) is the SOC content at the soil surface, k (m^{-1}) is the decreasing rate of SOC with depth (Eq. 1). In Eq. (2), s is the soil pH at the top of the profile, d is the soil pH at the bottom of the profile, k is the hillslope parameter representing the steepness of the increasing or decreasing trend of the transition zone, and α is the inflection point representing the midpoint the transition zone. In both equations, x (m) is the soil depth, and y is either the SOC content (kg m^{-3}) or soil pH at depth x .

Minasny et al. (2016) summarized seven different types of depth functions, including uniform, gradational, exponential, wetting front, abrupt, peak, and minimum-maximum. The depth functions developed can be used to understand soil formation and processes that occurred in the soil. The uniform distribution indicates little variation in the soil profiles which can be observed in young soil profiles where soil properties are similar to the parent material attributes. As soil development intensifies, other types of distributions can be observed for different soil properties. For example, as soil acidifies in the topsoil, soil pH distribution shows an

increase with depth. When a buried topsoil horizon (Ab horizon) is formed, a peak distribution can be observed for SOC content at the depth of the buried Ab horizon. The distribution of the elemental ratio of Ti/Zr (titanium/zirconium) has been used to indicate heterogeneity of parent materials because they weather slowly and can retain the characteristics of parent materials. The distribution of the elemental ratio of $\text{SiO}_2/\text{Al}_2\text{O}_3$ (Silicon dioxide/Aluminium oxide) has been used to indicate the rate of weathering in the soil profile, as Si is a mobile element and can be easily weathered and leached, while Al is an immobile element and can accumulate during weathering. An example of the vertical distribution of Ti/Zr and $\text{SiO}_2/\text{Al}_2\text{O}_3$ in a Mollisol is shown in Fig. 5, where the soil was formed in two different parent materials in the 1-m profile—aeolian deposits (loess) over glacial outwash (Zhang and Hartemink, 2019c).

By fitting a depth function to few observations, we can predict soil properties at any depth. It has been used to model the vertical variation of soil in 3-D maps. The exponential decay function has been used for 3-D SOC mapping in which the parameters of the function are interpolated to unsampled locations to reconstruct the vertical distribution of SOC at new locations. The development of proximal sensing tools markedly increases the sampling density in soil cores or vertical transects. The pXRF spectroscopy measures elements (e.g., Si, Al, Fe, Ca, Ti, and Zr), closely related to soil weathering and parent material. The vis-NIR spectroscopy can predict soil properties related to organic components and soil mineralogy. The use of these two instruments improves the ability to derive continuous depth functions of many soil properties and to understand soil formation and processes in soil profiles. In addition, it can be potentially used to monitor the changes of depth functions of dynamic soil properties.

Soil profile mapping

Soil properties vary horizontally and vertically in the profile; however, the horizontal variation is understudied within a soil profile compared to the vertical variation. Digital soil mapping techniques have been applied on soil profile walls to map the 2-D variation in soil properties. To generate a soil profile map, soil samples are first collected from a grid with 10-cm or 20-cm intervals across the soil profile wall and analyzed for soil properties. These samples often have a spatial resolution that does not capture the variation within the 10-cm or 20-cm intervals. Geostatistical methods (e.g., ordinary kriging with point or block support to produce maps, contour mapping) can be applied on these coarsely collected samples to interpolate the soil property values to generate 2-D fine-resolution soil maps.

Along the lines of landscape-scale soil mapping, environmental covariates can be used in machine learning methods to improve the mapping accuracy and spatial resolution on soil profile mapping. Digital images of soil profiles are the most common and readily accessible covariates that have high spatial resolution and convey soil color, soil texture, carbon content, iron oxides, coarse fragments, and redoximorphic features. Soil profile images have been combined with soil properties using the random forest method to map the 2-D variation of soil carbon, soil texture, and weathering indices (Zhang and Hartemink, 2019a). Hyperspectral

images are high-resolution 2-D images where each pixel consists of a vis-NIR reflectance spectrum with a spectral range of 400–1100 or 350–2500 nm instead of RGB color (Steffens and Buddenbaum, 2013). The hyperspectral images, comparable with vis-NIR spectra, contain more information on soil properties compared to digital images and are good variables for soil profile mapping. It has been used with machine learning methods to map the variation of soil carbon, nitrogen, clay content, elemental concentrations, hematite, calcite, salt, and water content of soil profiles. An example of profile mapping of organic matter fractions, Fe, and Mn in a Luvisol (Alfisol) using the hyperspectral image is shown in Fig. 6.

The generated soil profile maps display the distribution of soil properties in the profile and improve the quantification of variation in soil horizons. These maps can be used to investigate pedological processes and weathering conditions of soil profiles and have been used in fuzzy clustering to identify soil horizons objectively and to quantify soil horizon purity and variation. These maps provide more detailed information and more accurate measurements on soil profile properties, and provide a strategy to characterize fine-resolution and deep soil features. The soil profile mapping technique has been used repeatedly on soil profile walls to monitor soil processes. For example, the hyperspectral camera has been used to take soil profile images continuously over 5 days after a rainfall event and the generated soil profile maps can monitor the movement of salt in the soil profile (Wu et al., 2018).

Many geophysical techniques have been used to characterize or map the horizontal and vertical variation of soil profile and soil transects in a non-destructive way, that is, without digging a soil pit. Electromagnetic induction instruments can measure the soil's apparent electrical conductivity (ECa) from the soil surface down to approximately 6 m. Soil ECa is influenced by many soil properties, such as soil moisture, clay, and salt, and therefore, can be used to estimate these soil properties through calibration models with individual soil properties. This technique has been used to map the soil moisture content along a 350-m transect and to delineate soil moisture dynamics and soil-drying process during evapotranspiration (Huang et al., 2017). Ground penetrating radar measures the dielectric constant of soil which is influenced by soil moisture, organic matter, bulk density, and texture. It can generate 2-D images of soil profiles for characterizing its variation, identifying different soil horizons, estimating depth-to-bedrock, and monitoring the movement of water or solutes.

Soil sampling

Soil samples collected from soil profiles for laboratory analysis are taken to represent variation within the profile. Since the variation is mostly observed in the vertical direction, the soil profile is usually divided into soil horizons or layers from where the soil samples are taken. Soil samples are either collected from horizon centers or mixed from the entire horizon to represent the soil property of the corresponding horizon. Soil samples collected in this way requires accurate delineation of soil horizons, but it does not capture the variation within soil horizons and disregards the horizontal variation. In some studies, soil samples are collected from fixed depth intervals (e.g., 10-cm interval) in soil cores. This method is convenient for recording and is often used for large-scale soil mapping. In other studies, more samples are collected at small intervals in the topsoil which is more sensitive to human activities and climate change, and fewer samples are collected in deep soils which are more static.

To capture the 2-D variation of soil profiles, other sampling methods have been developed to complement the current sampling schemes in the vertical direction. Raster sampling with a fixed interval (e.g., 10-cm, 15-cm) gives the best coverage of the soil profile. This method is mainly used to collect samples for 2-D soil profile mapping. But, it is time-consuming and labor-intensive. To reduce the sampling effort, a few vertical transects can be collected to cover the horizontal variation of the soil profile, such as collecting three transects from left, middle, and right of the profile. Jones (2017) performed a variogram analysis of proximally-sensed data of 15 soil profiles and found that the variation in soil property variance is stable with depth. This finding means that a soil profile should be sampled with equal density in the topsoil and subsoil. The lateral variance in soil properties of the soil profile is much less than the vertical variation. A 4-cm vertical increment is equivalent to the variance experienced over an entire 1-m lateral cross-section of the profiles.

Other available variables (e.g., color information from digital images) can be used to optimize the sampling scheme in soil profiles. It is based on the assumption that a good coverage in digital images (i.e., feature space) can largely guarantee a good coverage of soil profile variation. These variables can be used in conditioned Latin hypercube sampling or fuzzy *k*-means sampling to optimize the sampling scheme and reduce the sample size needed for covering the soil profile variation.

The development of proximal sensing tools reduces the sampling effort and increases the sampling density in soil profiles. Many soil properties can be rapidly predicted from proximal sensing tools, such as vis-NIR, MIR, and pXRF spectroscopy. This method expands the information obtained from soil profiles and captures more fine-scale soil variation. In some cases, soil modeling may be more accurate using densely estimated soil properties from proximal sensors compared to sparsely collected and measured soil data. Therefore, depending on different research objectives and required accuracy, one should determine the appropriate sampling schemes and proximal sensing techniques for soil profile sampling.

Applications

Digital soil morphometrics techniques and methods have improved the measurement accuracy and sampling density of soil profile attributes, and have provided more quantitative measurements of soil properties. These methods have found several practical applications.

Fig. 6 Soil profile mapping of organic matter fractions, Fe, and Mn in a stagnic Luvisol, greyic, silty. Steffens M and Buddenbaum H (2013) Laboratory imaging spectroscopy of a stagnic Luvisol profile—High resolution soil characterisation, classification and mapping of elemental concentrations. *Geoderma* **195–196**: 122–132.

Accurate assessment of SOC stock in soil profiles is important due to its essential role in biogeochemical cycling, food production, and climate change mitigation. Because of the laborious nature of sampling in deep soils and its cost, many studies sample only the top 30 cm and disregard the soil carbon in deep soils that is more recalcitrant because of less disturbance, leading to underestimating SOC stock. Most studies collect one soil core from each location, ignoring the horizontal variation of soils, leading to large uncertainty in estimates. The development of proximal sensing tools and advanced profile sampling schemes can increase sampling density without adding too much cost in soil analysis and thus result in a more accurate estimation of SOC stocks. Many soils contain coarse fragments, which should be subtracted when calculating SOC stock. The proposed profile imaging method to quantify coarse fragments in stony soils provides a fast and efficient way to account for coarse fragments for accurate assessment of SOC stock in soil profiles (Jiang et al., 2021).

Cropping and tillage practices affect soil properties, such as SOC content, nitrogen content, soil structure, and soil compaction, influencing plant growth. These effects behave differently for topsoil and subsoil. Accurate evaluation of these effects on soil properties is important for performing appropriate soil management practices. Studies have shown that proximal sensing tools improved the estimation accuracy of soil properties compared to sparsely collected soil samples. Hyperspectral imaging methods have been used to generate high-resolution profile maps of SOC, nitrogen, and clay content which provided more accurate information than collected soil samples when evaluating the effects of cropping systems on soil properties (Sorenson et al., 2020). The MLT scanner has been used to evaluate how the structure changes under different tillage practices in 27 soil profiles, which is more efficient and objective than the traditional way of identifying soil structure (Bagnall et al., 2020).

Soil physical properties (e.g., macropores) and physical processes (e.g., movement of water and solutes in the profile) are important in regulating many soil processes, such as water and nutrient uptake by plants, drainage, and transport of contaminants. Proximal sensing tools can monitor soil processes occurring in the soil profiles. The soil structure feature estimated from the MLT scanner was strongly correlated with soil hydraulic conductivity and can be used as a proxy of soil hydraulic properties (Eck et al., 2016). This technique can also be used to quantify macropores of soil. The hyperspectral imaging technique can take soil profile images rapidly with spectral information correlated with many soil properties. Therefore, it can monitor the dynamics of water and salt content of soil profiles after a rainfall or irrigation event.

Conclusion

Digital soil morphometrics uses proximal sensing techniques to measure and quantify soil profile attributes. Digital cameras, vis-NIR spectroscopy, pXRF spectroscopy, hyperspectral imaging, and 3-D laser scanner have been applied to quantify soil profile properties, including soil color, soil texture, soil structure, elemental concentration, coarse fragments, etc. Novel methods have been developed to delineate soil horizons and horizon boundaries automatically using proximal sensing tools and cluster analysis. The distribution and variation of soil properties in soil profiles have been quantified through 1-D continuous depth functions or 2-D soil profile maps. Digital soil morphometrics techniques and methods greatly improve the measurement accuracy and efficiency of soil profile attributes, contributing to a more accurate assessment of SOC stocks, evaluation of cropping and tillage practices on soil properties, and monitoring soil processes.

In future work, proximal sensors should be developed and tested for quantifying other soil profile characteristics, such as redoximorphic features, pores and roots. Sensor data fusion methods have the potential to quantify the soil profile attributes more accurately. Deploying the tools and methods to field condition increases measuring efficiency and advanced methods, such as deep learning, can be evaluated for automatic soil horizon delineation. A range of diverse soil profiles should be evaluated with the existing methods and new methods for soil horizon delineation and non-invasive tools could be evaluated for delineating soil horizons. Finally, standard procedures and guidelines may be developed for pedologists as a routine quantitative and analytical method for field soil description.

Abstract

Proximal soil sensing in the field is the application of handheld, ground, or vehicle-based sensors to obtain data when the sensor is placed in contact, or within 1–2 m proximity, of the soil. Proximal soil sensors operate as on-the-go, stationary, or stop-and-go systems, and cover a broad range of the electromagnetic spectrum. Field-based proximal soil sensors are a cheaper, less time and labor-intensive alternative to conventional laboratory analyzes, but are an indirect method that often requires site and time-specific spectral libraries and calibration models for meaningful interpretation. Multi-sensor data fusion and multi-sensor approaches are explored, alongside future directions.

Key points

- Proximal soil sensors are defined and classified according to their model of operation, with particular focus on applications in the field.
- Advantages and disadvantages of proximal soil sensing is discussed.
- Types and applications of on-the-go, point-based, and stop-and-go field-based proximal soil sensors are described.
- The development and importance of calibration models is highlighted.
- Multi-sensor data fusion and multi-sensor approaches are discussed.
- Future directions of proximal soil sensing are explored, including shifting technologies from the research to commercialization phases.

Introduction

Soil varies spatially across landscapes and with depth, and temporally both within, and between years. Understanding this spatial and temporal variation is crucial for a range of stakeholders, including land managers, farmers, and policy makers. Timely and accurate information describing soil variability is needed at increasingly finer (spatial and temporal) scales, but obtaining a representative sample of a particular soil landscape is an ongoing challenge (Adamchuk et al., 2004). While conventional soil sampling and laboratory analysis methods have contributed greatly to our scientific understanding of the soil landscape, they are

often laborious, time-consuming, and expensive (Viscarra Rossel et al., 2011). Sensor-based technologies, which can be used in the field can overcome these shortcomings and facilitate the acquisition of high-resolution soil data, allow better understanding of the spatial and temporal dynamics of soil.

Proximal soil sensing (PSS) in the field is the application of handheld, ground, or vehicle-based sensors to obtain data on (soil) properties when the sensor is placed in contact, or within 1–2 m proximity, of the soil (Viscarra Rossel and McBratney, 1998; Viscarra Rossel et al., 2010). The signals detected can be related to specific soil properties directly, or are proxies which require calibration. This definition of PSS excludes remote sensing via airborne or satellite platforms, and laboratory measurements with benchtop instruments.

Proximal soil sensors can rapidly provide users with cost-effective, detailed and timely information about soil physical, chemical, and biological properties (Viscarra Rossel et al., 2011). While some proximal sensors may not provide results that are as accurate or precise as conventional analyzes, per individual measurement, the collection of large amounts of (spatial and temporal) data via PSS offers users with more information than ever before about the soil landscape. Technological advances, improved accessibility, and reduced costs of PSS tools are contributing to an increased shift of PSS from the research-phase, to being implemented in more applied and commercial settings. The list of available PSS systems is expanding year-on-year, although the rate varies for different sensors, and in different areas globally.

This chapter focuses on PSS in the field and does not cover the use of proximal sensors in a laboratory setting. Types of proximal soil sensors, recent advances in commercialization, and their applications will be described. Multi-sensor approaches, sensor calibration and prediction will also be explored, including the future of PSS. Numerous reviews on the principles and applications of PSS for agriculture and natural resource management can be found elsewhere and are referred to throughout.

Sensor classification

Viscarra Rossel et al. (2011) classify proximal soil sensors into four main categories according to:

- The manner in which they measure (invasive [in situ or ex situ] or non-invasive);
- Their energy source (active or passive);
- How they operate (stationary or mobile); and
- The inference used in the measurement of the target soil property (direct or indirect).

Additional characterization criteria from Gebbers (2018) also classify proximal soil sensors according to:

- Their temporal responsiveness (the time taken for measurement, processing, and subsequent decision-making);
- Their selectivity (the extent to which a sensor can determine a particular property without interference); and
- Scope of the electromagnetic (EM) spectrum that they encompass (ranging from gamma-rays to mechanical methods).

Table 1 describes the classifications of common proximal soil sensors within the EM spectrum used in the field, and their applications to a range of soil properties.

Invasive sensors require a degree of sample preparation or direct contact (e.g., insertion into or extraction of the soil). Invasive in situ sensors measure soil properties in place, usually in direct contact with the soil (e.g., soil moisture sensors), whereas invasive ex situ systems require sample extraction and placement of the sample in contact with the sensing element for analysis (e.g., ion-selective electrodes) (Adamchuk et al., 2018). Non-invasive sensors measure from a proximal distance and do not require any sample preparation or processing (e.g., electromagnetic induction, EMI, sensors). Passive sensors measure ambient sources of energy (e.g., natural radioactive decay), whereas active sensor systems provide their own source of energy (e.g., ground penetrating radar, GPR) (Viscarra Rossel et al., 2011).

Proximal soil sensors operate as either on-the-go (mobile), stationary (point-based), or stop-and-go sensors (see section on types of sensors and their applications). On-the-go (mobile) sensors continuously collect data as they move across an area (e.g., EMI; Gebbers, 2018). Stationary sensors may be handheld (e.g., handheld infrared spectrometer) or permanently fixed sensors (e.g., a soil moisture probe buried in the soil), and must remain stationary during sample collection and measurement. Stop-and-go sensors can be moved from place-to-place, but need to remain stationary during sample collection and operate automatically (e.g., Veris®; see section on Stop-and-go sensors). Sensors that can provide data immediately (e.g., soil moisture or pH sensors) can be used for real-time management decisions (e.g., irrigation scheduling). If data processing, including cleaning and calibration, is required, sensors can be used for asynchronous applications (e.g., Digital Soil Mapping, DSM) (Gebbers, 2018).

Sensor selectivity indicates how well a sensor can determine a particular property without interference (Gebbers, 2018). High selectivity sensors (e.g., pH electrodes) are preferred, however there is a trade-off between sensor selectivity, cost, and robustness (Gebbers, 2018). Non-selective sensors such as EMI sensors, which measure electrical conductivity (EC), are widely used to assess a range of soil properties. While sensors that measure a physical process (i.e., direct measures) are most desirable, these are generally more expensive, less developed, and more technically demanding (Viscarra Rossel and Lobsey, 2016). Indirect methods, which rely on a proxy, are more readily available, more mature, and are cheaper to own and operate (Viscarra Rossel and Lobsey, 2016). However, these may be less accurate as they require site-specific calibration, are inherently more subjective (as they rely on proxies), and may be subject to inference from other soil constituents (Viscarra Rossel and Lobsey, 2016).

Table 1 Commonly used proximal soil sensors in the field and their relative position on the electromagnetic spectrum.

EM range wavelength (m)		Sensor type

The most commonly used proximal soil sensors in research, applied, and commercial settings are electrical and EM sensors (e.g., EMI), X-ray, optical and radiometric sensors (e.g., Gamma-rays, Near and Mid-Infrared spectroscopy), and capacitance probes (e.g., soil moisture sensors) (Table 1). Others sensor types not covered in detail in this chapter include acoustic, pneumatic, and mechanical sensors.

Advantages of proximal sensing

Proximal soil sensors can facilitate the (near-instantaneous) collection of high-resolution spatial (or temporal) data using simpler, less time and labor-intensive techniques compared to conventional laboratory methods (Viscarra Rossel et al., 2011). While data from proximal sensors may not be as precise as laboratory measurements (Viscarra Rossel et al., 2011), users are offered more information than ever before about the soils condition to characterize the (horizontal and vertical) spatial and temporal variability of soil properties (Viscarra Rossel and Lobsey, 2016) with minimal disturbance.

Disadvantages of proximal sensing

Many proximal sensors are indirect measures that rely on an inference of the relationship between the sensor signal (a proxy) and the properties of interest for meaningful interpretation. These calibrations and empirical relationships are, in many cases, specific to certain soil and environmental conditions that may change over time (Adamchuk et al., 2011). Thus, the use of proximal sensors is restricted to the soil conditions it has been calibrated for. Complex interactions and interrelationships between multiple soil properties limits the number of attributes that can be measured with a single sensor, and multivariate calibrations to account for these interactions and the non-specificity of some proximal sensor outputs may be required (Stenberg and Viscarra Rossel, 2010). The performance of different sensors varies considerably due to different soil and environmental factors, including soil parent material, water content, and temperature (Kuang et al., 2012), and the deployment of proximal sensors is limited by access to the area of interest. This is a particular issue on waterlogged soils (e.g., rice paddies) or in densely forested areas.

Types of sensors and their applications

Proximal soil sensors range from simple handheld, stationary systems, through to more complex, autonomous robotic sensor platforms and are in various stages of development and commercialization (Gebbers, 2018). Systems available “off the shelf” can be purchased directly and may be ready to use, or may require some additional development or calibration before use. Others are in mature stages of research where additional testing for implementation is needed, or remain in the ‘proof of concept’ phase. Advancements in sensor capabilities, and information and communication technologies (e.g., telemetry systems and cloud-based services) have aided the development of PSS systems and are contributing to their increased adoption in-the-field.

There are issues and opportunities associated with on-the-go, stationary, or stop-and-go systems that cover a broad range of the EM spectrum (Table 1).

On-the-go sensors

Logistical constraints limit the number of samples that can be obtained via conventional sampling strategies or point-based proximal soil sensors. Improvements in the quality, accuracy, and adoption of global positioning systems (GPS) and geographical information systems (GIS) within agriculture and landscape management as well as ever increasing computing power has supported more intensive soil sampling strategies and the rise of spatial on-the-go sensing and mapping. On-the-go sensing technologies enable the collection of high-resolution soil information and can facilitate the interpretation of soil spatial patterns using a more time and cost-effective method compared to conventional analysis techniques.

On-the-go (mobile) sampling presents the “ultimate solution” (Adamchuk et al., 2018) for collecting large amounts of data for spatial interpolation and decision making. On-the-go proximal soil sensors are typically mounted to tractors, all-terrain vehicles, or other farm machinery and measurements are recorded while continuously moving across a field (Fig. 1). Most commercial on-the-go PSS tools measure soil properties indirectly from on or above the soil surface, although sensor operation varies for different systems. The information collected is often used to derive maps of soil properties, which are then used as covariates for DSM or spatial interpolation methods.

Electromagnetic induction (EMI)

Electromagnetic induction is a noninvasive, ex situ soil sampling method, and is one of the most widely-used on-the-go PSS tools worldwide. Electromagnetic induction sensors measure the apparent bulk electrical conductivity of the soil (EC_a) through the transmission and reflection of EM waves between two or more electric coils (solenoids) (Gebbers, 2018), effectively turning the soil into an EM circuit. Soil properties that (directly or indirectly) influence conductivity can be inferred from EC_a measurements (via sampling and calibration), and the most common soil properties that are correlated with EC_a are soil clay content (texture), soil moisture, and salinity (Table 2; Whelan and Taylor, 2013). Calibrations are site and time-specific, which limits the application of EMI to the soil conditions it has been calibrated for. Readings are influenced by the soil’s water and salt content, temperature, and

Fig. 1 On-the-go Dual EM-21S electromagnetic induction (EMI) meter (Dualem Inc., Ontario, Canada) and RSX-1 gamma-ray spectrometer (Radiation Solutions Inc., Ontario, Canada) can be used as part of a multi-sensor platform to map soil moisture content and salinity (via EMI), and soil type and parent material (via Gamma). Together, these complementary sensors can be used to map patterns of soil variability, alongside a high-precision GPS unit mounted to the vehicle.

Table 2 General impact of soil properties on soil apparent electrical conductivity (EC_a) readings.

	Material	Soil texture	Clay type	Moisture potential	CEC	Salinity	Nutrients
Higher EC _a	Soil	Clay	Smectite	Saturated	High CEC	High EC	High N, P, K, Ca, Mg, Na
↑	Stony soil	Silt	Illite	Field capacity			
Lower EC _a	Rock	Sand	Kaolin	Wilting point	Low CEC	Low EC	Low N, P, K, Ca, Mg, Na

mineral type and composition, making universal calibrations complex and difficult to obtain (Whelan and Taylor, 2013; Doolittle and Brevik, 2014).

Compared to conventional sampling, EMI is a non-invasive, relatively quick, easy-to-use, cost-effective and data-rich measure of soil variability (Doolittle and Brevik, 2014). When coupled with data logging and GPS technologies, a high density of spatial data can be gathered on-the-go by surveying the area along transects or swathes (Figs. 1 and 2). Data is logged at regular (~1–3 s) intervals from (typically) ground-based vehicles at (potentially) multiple depths down to ~3 or 6 m for the most commonly used EMIs in soil science applications (refer to Fig. 1 for an example) (Viscarra Rossel et al., 2011), with effective sensing depth largely

Fig. 2 Gamma radiometrics K ROI and Soil EC_a (0–3 m) maps derived from a RSX-1 gamma-ray spectrometer (Radiation Solutions Inc., Ontario, Canada) and a Dual EM-21S electromagnetic induction (EMI) meter (Dualem Inc., Ontario, Canada), respectively, across “L’lara”, a property close to Narrabri in North West NSW, Australia. Gamma radiometrics primarily relate to changes in parent material and soil type, with high Gamma K values related to soils with a low soil moisture potential (i.e., wilting point), high cation exchange capacity and K content, and a shallow depth to rock/gravel. EMI relates to soil texture, moisture, and salinity, and high EC_a values generally relate to soils with a high moisture potential (saturated), high clay (smectite) content with a high nutrient (N, P, K, Ca, Mg, Na) content and EC. Together, these on-the-go soil measurements can be used to describe soil variability across a landscape.

determined by coil spacing, orientation, frequency, and height above the ground (Gebbers, 2018). Numerous EMI sensors are commercially available for use in the field, including the DUALEM (Duaem, Inc., Milton, Ontario, Canada) and EM38 (Geonics Limited, Mississauga, Ontario, Canada) meters. Each commercial sensor has operational advantages and disadvantages depending on the depths and soil properties of interest, the preferred data collection mode, and soil condition at the time of sampling (Sudduth et al., 2003).

Gamma-rays

Mobile gamma-ray spectrometry (GRS) is a noninvasive, ex situ soil sampling method used to estimate the concentrations of naturally in the soil occurring radioelements (Potassium [^{40}K], Uranium [^{238}U], Thorium [^{232}Th], and their ratios) below the earth's surface (Reinhardt and Herrmann, 2019). This is done by measuring the gamma rays of radioactive isotopes emitted during radioactive decay. Passive and active gamma ray sensors are available, although passive gamma-ray sensors are preferred due to radiation and safety concerns associated with active sensors, which provide their own source of radiation (Adamchuk et al., 2018).

Simple gamma-ray sensors detect bulk radiation (total count), while others can distinguish different energy levels (Gebbers, 2018). Three key regions of interest (ROIs) in the gamma spectra (^{40}K , ^{238}U , and ^{232}Th) are commonly used to (directly and indirectly) infer information for understanding land forming processes and soil attribute distributions; primarily for parent material characterization and soil type differentiation (Table 3; Whelan and Taylor, 2013; Reinhardt and Herrmann, 2019). Direct, standalone total count readings may be sufficient for delineating basic patterns of soil variability, but a more detailed interpretation and relation to specific soil properties requires sophisticated data processing (Pätzold et al., 2020).

Gamma counts can be logged continuously on-the-go while driving over an area (Figs. 1 and 2). Approximately 90% of all aboveground gamma radiation originates from the upper 30–50 cm of the soil profile (Gebbers, 2018), although effective depth largely depends on bulk density and moisture content (Reinhardt and Herrmann, 2019). As for EMI, GRS enables the fast collection of dense spatial data and has a relatively well-established theoretical background (Gebbers, 2018). However, careful site- and time-specific calibrations are required to account for different geopedological conditions (Pätzold et al., 2020). The most common commercially available gamma-ray sensors for use in the field include the RS-X (Radiation Solutions Inc., Ontario, Canada) and the Medusa (Medusa Radiometrics BV, Groningen, The Netherlands) gamma-ray spectrometer series.

While EMI and Gamma-ray spectrometer readings can be used individually to create soil property maps (e.g., soil EC_a , cation exchange capacity (CEC), soil texture), these maps are often difficult for users to understand and are not useful for making management decisions. Instead, on-the-go EMI and Gamma-ray sensors are often used in combination to map variability across the soil landscape and diagnose potential constraints and limitations (Fig. 2). Gamma-ray spectrometer readings are largely impacted by shallow rocky materials, and total-count values are high in soils with a large clay (smectite), CEC and K contents, and a low soil moisture potential (i.e., wilting point). Soil EC_a readings (from EMI) are primarily related to soil texture, moisture, and salinity. High EC_a values relate to soils with high moisture potential (saturated), and large EC, clay (smectite), and nutrient (N, P, K, Ca, Mg, Na) content. The inverse response of these two soil measurements to soil moisture content, salinity status, and rocks/stones means that they can be used together to identify the causal factors of high EC_a readings (whether that be soil moisture, salinity, clay, or CEC), and identify patterns of variability. For example, low gamma counts are associated with sandy soils, and EMI can be used to determine if these sands are saline or not. These instruments are often used in tandem as part of a multi-sensor platform (Fig. 1).

COSMOS

Cosmic-ray Neutron Sensing (CRNS; Zreda et al., 2008) is a passive, non-invasive, indirect soil sensing tool used to estimate soil moisture based on the inverse relationship between the intensity of naturally occurring cosmic-ray generated neutrons, and the amount of water present in the surrounding environment (Desilets et al., 2010). While CRNS probes are used within agricultural fields and as part of larger soil moisture monitoring programs (i.e., the COsmic-ray Soil Moisture Observing System, COSMOS; Zreda et al., 2012), this stationary data does not capture the inherent spatial heterogeneity of soil moisture at a range of scales. A ground-based, mobile CRNS, called the cosmic-ray rover (Desilets et al., 2010), has been used for spatial soil moisture surveys over large areas (Fig. 3). However, there are few cosmic-ray rovers across the world, and they are not available commercially. As for all

Table 3 General impact of soil properties on soil gamma emission (total count; TC).

	Material	Soil texture	Clay type	Moisture potential	CEC	Depth to rock or gravel	Nutrients
Higher TC	Rock	Clay	Smectite	Wilting point	High CEC	Shallow	High K
	Stony soil	Silt	Illite	Field capacity			
Lower TC	Soil	Sand	Kaolin	Saturated	Low CEC	Deep	Low K

Fig. 3 Example of a mobile cosmic ray neutron sensing (CRNS) system, the 'CosmOz Rover'—CSIRO (<https://cosmoz.csiro.au/about>), operating in the field (a) and a view of the cosmic-ray neutron sensors inside the trailer. The CosmOz Rover has a counting rate equal to about 20 standard stationary cosmic-ray probes, which enables the collection of the spatial variation in neutron counting rates while driving the trailer through the landscape.

indirect soil sensing methods, site and time-specific calibrations are required to account for local conditions at the time of sampling. The calculation of volumetric soil moisture content requires information on the spatial variation of bulk density, soil organic matter, and lattice water (i.e., the amount of hydrogen held within the lattice structure of the soil minerals), which requires spatial data at an appropriate scale or additional spatial sampling to collect the necessary information. Vegetation cover and roads can also influence soil moisture readings from mobile cosmic-ray sensors (McJannet et al., 2017).

Time-domain reflectometry (TDR) and ground-penetrating radar (GPR)

Time-domain reflectometry (TDR) and ground-penetrating radar (GPR) are active sensors that operate based on the soil's dielectric constant (or the soil's ability to store electrical charge), and can be related to soil moisture. Both TDR and GPR rely on the same principle in that they measure the travel times and amplitudes of an EM pulse (Corwin, 2008; Gebbers, 2018). However, TDR uses two (or more) buried electrodes that are in direct contact with the soil, while GPR operates indirectly above the soil surface (Gebbers, 2018). TDR sensors are mainly used for stationary measurements, but prototype stop-and-go mobile TDR sensors have been developed (Thomsen et al., 2007) and more work is needed to further develop and commercialize continuous mobile TDR measurements (Gebbers, 2018). Mobile GPR sensors are commercially available and are predominately used for geophysical exploration and hydrology (Knight, 2001).

Soil compaction and strength

In addition to proximal soil sensors that operate within the EM spectrum, soil compaction, impedance or strength can be measured on-the-go or at a single point via mechanical approaches. Mechanical sensors either measure the amount of energy required to pull an implement through the soil (e.g., tine), or measure the resistance of the soil to the insertion of a probe (penetration resistance) (Adamchuk et al., 2018). Broadly, any soil tillage tool (e.g., plows, load cells) can be used to measure the spatial variability of soil strength and compaction at single or multiple depths, and are relatively inexpensive, robust, and easy-to-use. Acoustic and pneumatic sensors may also be used to assess soil structure and compaction.

Point-based sensors

Point-based, or stationary, proximal sensing systems can be operated in the field to make a single measurement, produce several measurements at different depths at a given location, or continuously monitor soil parameters when installed at a site for a period of time (Adamchuk et al., 2011). These may be handheld sensors, which can be moved from site-to-site (e.g., handheld infrared spectrometers), or be permanently fixed sensors, and must remain stationary during sample collection and analysis. Although point-based proximal sensors have a smaller spatial sampling density compared to on-the-go and stop-and-go systems, the ability to continuously monitor soil properties and understand their temporal dynamics (Adamchuk et al., 2018) means that they are an important component of proximal sensing repertoire for farmers and land managers.

Visible, near and mid-infrared diffuse reflectance spectroscopy

Diffuse reflectance infrared spectroscopy (DRS) is a proven method for rapid soil characterization under soil laboratory conditions (Stenberg et al., 2010) and with the development of field portable systems is slowly emerging for the rapid and cost-effective analysis of soil physical, chemical, and biological properties in field settings (Stockmann et al., 2018). Infrared spectroscopy is based on the reflection, absorbance, and scattering of light (photons) to measure soil properties, based on characteristic peaks or valleys at certain wavelengths in the visible (vis; 390–700 nm), near-infrared (NIR; 700–2500 nm), and mid-infrared (MIR;

2500–25,000 nm) parts of the electromagnetic spectrum. Spectral reference libraries, which are collections of known relationships between spectra and soil properties, are key to DRS. Calibration models are developed from these reference libraries to produce predictions of soil properties at varying levels of accuracy (Soriano-Disla et al., 2014). Additional pre-processing transformations may also be required to reduce noise, address the effects of field condition scanning such as soil moisture (e.g., external parameter orthogonalization, EPO; Minasny et al., 2011), and enhance more chemically-relevant peaks (Stenberg and Viscarra Rossel, 2010). Applications of DRS in research and commercial settings is increasing because it is a rapid, non-destructive, less labor-intensive, and more cost-effective alternative to conventional laboratory analyses alone. There is a growing number of portable, handheld NIR spectrometers being developed and made available commercially for soil sensing applications (Tang et al., 2020), including from Hone Carbon (<https://www.honecarbon.com/>) and Yard Stick (<https://www.useyardstick.com/>), which can both be used to measure soil carbon levels in the field (Fig. 4). However, developing representative and diverse spectral libraries for these technologies remains a challenge at present for widespread commercial uptake.

Portable X-ray fluorescence spectrometry

Portable X-ray fluorescence (PXRF) spectroscopy is a widely used, non-destructive, indirect proximal sensing tool used to determine the elemental composition of a sample, based on the excitation and release of energy from electrons. X-ray fluorescence spectrometers emit X-rays which are absorbed by electrons and shift them into an excited energy state, resulting in the release of X-ray energy which is referred to as X-ray fluorescence. This measured energy spectrum (fluorescence) contains peaks that are characteristic for each element, and this X-ray absorption can be used to identify and quantify different elements in a sample (Weindorf et al., 2014; Gebbers, 2018). Robust PXRF instruments can quantify up to 42 elements (Gebbers, 2018), but the detectable range is greater for more sophisticated instruments. XRF spectroscopy is an established laboratory method in earth sciences, and field-based, handheld PXRF instruments are increasingly becoming available at decreasing prices (Gebbers, 2018). Field PXRF spectrometers enable the rapid, relatively easy, *in-* and *ex situ* analysis of solid soil samples with minimal sample preparation compared to conventional laboratory analysis and are commonly used for land contamination assessments (Pozza et al., 2020). However, invasive site-preparation is still necessary to prepare soil pits or extract cores for scanning (Weindorf et al., 2014). As for other indirect methods, there are several sources of interference on PXRF signals mainly soil matrix heterogeneity, but also soil moisture content, and thus the degree of sample preparation (Weindorf et al., 2014), although PXRF is less impacted by soil moisture than is DRS.

Fig. 4 Predictions of Soil Organic Carbon (SOC) % using the Hone Lab Red sensor from 0 to 50 cm at 5 cm increments (dark grey) in four locations across the CSIRO Boorowa Agricultural Research Station long-term trial site in NSW, Australia, using a local calibration model with 50 samples produced through an ensemble cubist model with 50 bags. The prediction interval (light grey) is also shown and observed SOC analytical values are presented in black. Soil moisture sensors

Proximal soil moisture sensors may directly or indirectly measure soil moisture content from above the soil surface or via direct contact. Stationary soil moisture sensors can be used to take single measurements, multi-depth measurements, or continuously monitor soil moisture at a given location. Linking numerous moisture sensors together via wireless networks can also be used to monitor the spatial and temporal dynamics of soil moisture (Adamchuk et al., 2018). Many soil moisture sensors are relatively mature technologies, and commonly used proximal soil moisture sensors in the field include capacitance probes and frequency domain reflectometry (FDR) sensors, matric potential sensors, active neutron probes and gamma-ray sensors, and passive cosmic-ray sensors.

Capacitance probes and FDR sensors are both active, invasive sensors that measure soil moisture content based on the soils dielectric constant by propagating an EM wave through the soil (i.e., using it as a dielectric medium). Matric potential sensors (e.g., tensiometers, gypsum blocks, and granular matrix sensors) measure the amount of force (suction) required to extract water from the soil (i.e., the soils matric potential), rather than the soil moisture content (Hardie, 2020). Capacitance, FDR, and matric potential sensors all require direct soil-to-sensor contact to obtain accurate readings, and the measurement area (i.e., the volume of inference around the sensor) is relatively small (Hardie, 2020).

Other field-based, stationary soil moisture sensors include active neutron probes and gamma-ray sensors, and passive cosmic-ray sensors. These noninvasive sensors all facilitate the fast, accurate, and continuous monitoring of soil moisture at a fixed point, and are particularly well-suited to hard-set, vertic (shrink-swell) soils where the installation of other soil moisture sensor types is difficult (Hardie, 2020). However, they are costly, require complex and precise calibration methods, and the measurement footprint of cosmic ray neutron sensors in particular (i.e., 200–600 m) means they are poorly suited to short-range precision agriculture treatments such as variable rate irrigation (Hardie, 2020). Further, application of active neutron and gamma-ray sensors in the field is limited due to radiation safety concerns.

Stop-and-go sensors

Stop-and-go sensors can be moved from place-to-place, but the sensor platform needs to remain stationary during sample collection. While sampling locations and intervals are typically defined by the user, the sample collection itself is often automated into the sensor platform once the vehicle has stopped. Stop-and-go platforms usually have a smaller sampling density compared to on-the-go systems but are greater than conventional sampling methods or point-based proximal sensors. Multiple sensors may be incorporated onto a single stop-and-go sensor platform for the collection of several measurements at once, and modular systems which enable the customization of sensor platforms are increasingly being adopted.

The uptake of single-vendor, modular sensing systems is increasing in applied and commercial settings. A range of on-the-go, stop-and-go, and point-based proximal soil sensors are commercially available and marketed by Veris® Technologies (Salina, USA; <https://veristech.com/>). Depending on the platform and its configuration, modular sensing systems like Veris® integrate a range of proximal sensors, such as EMI, infrared spectrometers, and penetrometers, to measure a range of soil properties in the field using a multi-sensor approach, including soil pH, EC, and soil organic matter. Sensors may be mounted on existing farm equipment, embedded within a complete sensing system, or be individual sensors that can be used in combination within a customized setup. For all Veris® sensors, sample uptake, analysis, and sensing is automated on-the-go or within a stop-and-go system. Single vendor, modular systems are widely used in research and commercial applications as they require little-to-no user calibration and configuration, provide a high-density of information to map soil properties, and are relatively easy to use and interpret.

Other automated stop-and-go proximal sensing systems are incorporating spectrometers into multi-sensor platforms. The Soil Condition Analysis System (SCANS) is an automated soil core sensing system which measures a range of soil properties (e.g., SOC, bulk density, pH, available water capacity) of an intact soil core under field condition using a complementary set of sensors covering different portions of the EM spectrum (i.e., a gamma-ray attenuation densitometer, digital camera, and a vis-NIR spectrometer) (Viscarra Rossel et al., 2017). For field deployment, soil cores are extracted and loaded manually into the SCANS platform which is mounted within a specialized field trailer, and the sample is scanned automatically along the core (Fig. 5). The modularity of SCANS can also facilitate the integration of other sensors (e.g., portable XRF and mid-IR spectrometers) as they become available (Viscarra Rossel et al., 2017).

Predicting soil properties

Calibration and spectral libraries

Many proximal sensors are indirect measures and parameter values cannot be directly deciphered from sensor signals or spectra. Instead, spectra need to be related to known reference samples, collectively known as a spectral library, through calibration of a prediction model (Stenberg and Viscarra Rossel, 2010). These reference samples must be representative of the range of soil types and conditions that the model and sensor is intended for. Commonly used calibration models include stepwise multiple linear regression, principal component analysis, partial least squares regression, and machine learning methods (e.g., regression trees). Also, additional pre-processing using mathematical functions is often used to correct for variation (e.g., normalizing spectra in respect to each other using pre-processing methods such as the Standard Normal Variate (SNV) method) and reduce noise (Stenberg and Viscarra Rossel, 2010).

Fig. 5 (a) The trailer-mounted SCANS automated proximal sensing system at a field site. (b) The soil core sensing system collecting data down the length of a soil core through a gamma densitometer, vis-NIR spectrometer, and high-resolution RGB camera.

Spectral libraries and calibration models enable predictions on unknown samples using only spectral data, saving both time and money compared to conventional laboratory assessments. However, the construction of a representative and diverse soil spectral library still requires conventional soil sampling and analysis which is both site- and time-specific. While fewer calibrations are better in terms of logistics, cost, and error, there is a trade-off between the accuracy of this calibration data and generalization capacity (Stenberg and Viscarra Rossel, 2010). Further, sensor signals respond to multiple factors that depend on environmental conditions (e.g., soil moisture) and diverse reference samples or libraries are needed to account or correct for this variability.

Multi-sensor data fusion

No single sensor can measure all soil properties, and sensors can respond to more than one soil or landscape attribute. Using a selection of complementary sensing techniques and integrating this data, through multi-sensor data fusion or via a multi-sensor approach, presents an opportunity to provide more information about soil properties (Adamchuk et al., 2011).

Multi-sensor data fusion, or the use of two-or-more sensors and their subsequent data, can improve the quality and diversity of information that would otherwise not be available, or not be as accurate, from individual sensors (Adamchuk et al., 2011). Spectral reference libraries and calibration models are used to define relationships between sensor signals and soil attributes, including multivariate models or machine learning algorithms (Adamchuk et al., 2018). Different combinations of sensor inputs and models may be necessary depending on the target soil property, including the concatenation of spectra or model averaging of predictions from sensors across different areas of the EM spectrum (Pozza et al., 2020).

Multi-sensor approaches involve the use of multiple sensors in tandem for unique applications and output. Multi-sensor approaches can increase the robustness and validity of measurements, capture a broader range of soil attributes, and increase the density of data collected (Adamchuk et al., 2011) by using multiple sensors across the same area at the same time, often in a single pass for on-the-go or stop-and-go sensors. Within these multi-sensor platforms, sensor configuration may be complementary (i.e., information from two-or-more sensors can give a more complete image of the environment when used together), competitive (i.e., multiple sensors deliver independent measurements of the same property, often used to increase robustness or reduce error), or cooperative (i.e., use two-or-more sensors to derive information that would otherwise be unavailable from a single sensor as part of multi-sensor data fusion) (Durrant-whyte, 1990; Mitchell, 2012). Modular multi-sensor systems like Veris® (refer to section on Stop-and-go sensors) are an example of a multi-sensor approach that is used in commercial settings to gain a more complete understanding of the soil landscape.

Future directions of proximal sensing

In practice, proximal soil sensors are not a standalone tool. Instead, they form part of a complex decision-making process that draws information from a range of sources (Society of Precision Agriculture Australia (SPAA), 2017). Data integration from across multiple PSS systems and other on-farm (e.g., yield monitor data), remote sensing (e.g., LANDSAT, MODIS), and publicly available (e.g., ELVIS—Elevation and Depth—Foundation Spatial Data) data platforms can provide users with a thorough understanding of the soil landscape. Maps derived from PSS tools, such as soil gamma radiometric or EC_a maps, are often used as covariates for design-based soil sampling, DSM and spatial interpolation methods, alongside this additional auxiliary information. The acquisition, integration, and presentation of information from various sources can aid in the assessment of soils at a range of spatial and temporal scales, and can help to assess the uncertainty of proximal sensing predictions. Beyond this, PSS tools can also be used to guide future soil sampling strategies, such as delineating agricultural management zones or areas of land contamination (Society of

Precision Agriculture Australia (SPAA), 2017). However, further research on the complementary use of multi-sensor information and spatial (up and down) scaling of this data is needed (Viscarra Rossel and Lobsey, 2016).

For several soil attributes, appropriate proximal sensors remain in the research phase. However, greater commercialization potential is being realized as the cost, accuracy, and ease of use of these sensors continues to improve. To increase the uptake and application of PSS tools, better access to commercialized and integrated PSS systems and services is required (Viscarra Rossel and Lobsey, 2016). Further, integrating this information with other on-farm, industry, and publicly available data to enable meaningful interpretation needs to be supported. It should be emphasized that investment, research, and development into new and improved PSS tools should not be for the sole purpose of collecting more data. These tools should be used to collect information that is relevant to farmers, land managers, policy makers and other stakeholders that need data to support well-informed management and policy decisions. The translation of existing information into accessible tools for all end-users is an important first step to better understanding the soil landscape.

Abstract

Soil moisture (SM) is of paramount importance for society and the global environment. Accurate SM information is at the core of a plethora of applications that include forecasting of weather and climate variability, projection and monitoring of drought conditions, precise agricultural irrigation management, conservation of water resources, monitoring of ecosystem response to climate change, and impact mitigation of natural disasters such as wildfires, landslides, floods, or dust storms, whose occurrence is intimately connected to the moisture status of the land surface. Variations in SM can have substantial impacts on ecosystem health, agricultural productivity, and forestry. In this chapter we present state-of-the-art and novel technologies and sensors for proximal sensing of SM together with the underlying concepts and theories.

Key points

- State-of-the-art and novel technologies and sensors for proximal sensing of soil moisture (SM) are presented.
- The underlying concepts and theories for proximal SM sensing are discussed.

Introduction

Soil moisture (SM) is a key hydrologic state variable that is of momentous importance for numerous applications in the agricultural and environmental sciences. The importance of SM is emphasized by the Global Climate Observing System (GCOS) (<https://gcos.wmo.int/>) Terrestrial Observation Panel for Climate (TOPC), who designates SM as an Essential Climate Variable (ECV) of the hydrosphere. Soil moisture is a governing variable with respect to partitioning the solar radiation impinging the land surface into latent and sensible heat fluxes, and separating precipitation into infiltration, runoff, and subsurface flow. SM controls the feedbacks between soil, vegetation, and climate and determines the prevailing vegetation cover and distribution within a region. Detailed knowledge about the state of SM and its spatial and temporal dynamics is of crucial importance for crop production, not only to prevent water stress and sustain yields, but also for the mitigation of adverse environmental impacts due to over-irrigation as well as for the conservation of water resources. The latter is especially relevant in view of the water crisis and prolonged drought conditions in many arid and semiarid regions of the world that is expected to escalate further due to the rapidly increasing human population and the changing global climate. Another area of application is the mitigation of the impact of natural disasters such as wildfires, landslides, floods, or dust storms. The potential of their occurrence is intimately connected to the SM status of the land surface. For example, when the SM diminishes below a certain threshold (i.e., the soil surface dries out) on land with sparse vegetation and the atmospheric conditions are favorable (i.e., strong winds and low relative humidity), a dust storm may develop. The frequency of dust storms in the Southwestern United States is increasing, causing chronic breathing and cardiovascular problems for humans, and exposing both humans and animals to fungal spores that can lead to potentially fatal valley fever (coccidioidomycosis). Today, a growing number of proximal techniques are available to measure and monitor the spatial and temporal SM variability. At the pedon scale, electromagnetic soil moisture sensors based on travel time-, capacitance-, or impedance-based measurement principles are used to record changes in SM. The latest generation of electromagnetic sensors incorporate microelectronic measurement

circuitry together with a microprocessor directly in the sensor head and communicate processed data to a datalogger. The cosmic-ray neutron probe (CRNP) is another promising invention that infers soil moisture for an approximately 300-m circular footprint from counting neutrons generated when naturally-occurring cosmic rays interact with hydrogen atoms in the topsoil. There are also several proximal geophysical sensing methods such as ground penetrating radar (GPR), electromagnetic induction (EMI), and nuclear magnetic resonance imaging (NMRI) deployed for field scale measurements of SM dynamics. Moreover, microwave radiometry has been successfully employed for proximal SM determination.

Definition of soil moisture

The SM or soil water content, which may be expressed in gravimetric (θ_m) or volumetric (θ_v) terms, represents the amount of water present in the soil at a given matric potential ψ_m . The ψ_m is synonymous with the combined capillary and adsorptive surface forces that hold water within the solid soil matrix and are uniquely related to SM under hydrostatic conditions. The decidedly nonlinear relationship between SM and ψ_m is termed soil water characteristic (SWC) curve or soil water retention (SWR) curve, which shows a very distinctive shape for each individual soil texture (Fig. 1).

The gravimetric SM, θ_m (kg kg^{-1}) is the ratio of the mass of water within a soil sample and the mass of the oven-dry solid material. The volumetric SM, θ_v ($\text{m}^3 \text{m}^{-3}$), defined as the volume of water within a given soil volume may be expressed in terms of θ_m as (Babaeian et al., 2019):

$$\theta_v = \theta_m \left(\frac{\rho_b}{\rho_w} \right) \quad (1)$$

where ρ_b is the dry bulk density (kg m^{-3}) of the soil, and ρ_w is the density of water (kg m^{-3}). When all soil pores are filled with water, θ_v is named saturated water content θ_s (Fig. 1). Sometimes, SM is expressed in terms of relative saturation, $S_e = \theta_v / \theta_s$, which is the volumetric SM content normalized to θ_s . Conceptually, the range for S_e is from zero, when the soil is entirely dry, to one, when all pores are filled with water. However, it is impossible in nature for soils to exhibit complete dry or saturated conditions. There is always residual moisture θ_r (Fig. 1) in soil pores under dry conditions and it is not possible to completely de-air soil because cavitation nuclei are tightly held in crevices of rough particle surfaces and air bubbles remain entrapped in dead-end pores. To account for θ_r , S_e may be expressed as:

$$S_e = \frac{\theta_v - \theta_r}{\theta_s - \theta_r} \quad (2)$$

The maximum S_e range is from approximately 0.94 to 0.97 (–) for fine-textured (clay) and coarse-textured (sand) soils, respectively.

It is convenient to express SM in length units for water balance applications to be consistent with other variables such as precipitation or evapotranspiration. This so-called equivalent depth of wetting may be obtained by multiplying θ_v with the depth of the soil layer of interest.

For agricultural irrigation management, a plant available water content (θ_{PAW}) is often defined as the difference between the water content at field capacity (θ_{FC}) and the water content at the permanent wilting point (θ_{PWP}) (Fig. 1). The θ_{FC} is synonymous

Fig. 1 The SWC curve shown for different soil textures. The markings pertain to the silt loam soil curve.

with the water content after internal redistribution of water within the soil matrix due to gravity (free drainage) and for practical purposes is often assumed to coincide with a matric potential of -3.3 m. This definition is not entirely correct as θ_{FC} depends on soil texture. The θ_{FC} for a sandy soil, for example, more likely corresponds to $\psi_m = -1$ m. Below the θ_{PWP} that is defined as the water content at $\psi_m = -150$ m, water is so tightly bound within the soil matrix that plants are no longer able to recover their turgidity and irreversibly wilt. Again, this is only an approximation, because the permanent wilting point depends on the physiology of plants. Desert plants, for example, can withstand significantly lower matric potentials (drier conditions).

Proximal sensing

Proximal sensing encompasses the acquisition of signals from the soil with sensors that are either in direct contact with or in close proximity to the soil (Viscarra Rossel et al., 2011). Proximal sensors may be further categorized based on the mode of deployment (i.e., stationary, or mobile), their source of energy (i.e., active or passive), the method of installation (i.e., invasive, or noninvasive), and based on how the soil property of interest is determined from the measured variable (i.e., direct, or indirect). An electromagnetic Time Domain Reflectometry (TDR) SM sensor, for example, is considered as invasive, stationary, active, and indirect—TDR infers θ_v from the soil's dielectric permittivity (Viscarra Rossel et al., 2011).

Electromagnetic soil moisture sensors

As early as in the 1960s electromagnetic-based instruments with 30 MHz frequency have been employed for soil moisture determination using fringe capacitance (Thomas, 1966). Soil water content sensing was truly revolutionized by Topp et al. (1980) with the introduction of time domain reflectometry (TDR). Early TDR systems were costly and initially only used in laboratory settings. Forty plus years later, the costs of TDR sensors have decreased by several orders of magnitude. At the same time, capacitance- or impedance-based circuits have also become popular for water content measurements. As a result, numerous electromagnetic (EM) sensors (Fig. 2) that use the permittivity of soil for water content determination are available today (Jones et al., 2005; Vaz et al., 2013). The permittivity or dielectric constant is the electrical potential energy of a porous material (e.g., soil) under the influence of an electromagnetic field. The sensor's electromagnetic field is directed into the soil along 2-, 3-, or 4-parallel rods or into adjacent pairs of rings. The HydraProbe (Stevens Water Monitoring Systems Inc., Portland, OR, USA), one of the most widely used EM sensors in the United States, consists of one central and three outer electrodes (Fig. 2A), and relies on a 50 MHz impedance circuit. It is deployed by U.S. federal agencies for weather and snow monitoring stations such as the Soil Climate Analysis Network (SCAN), or SNOWpack TElemetry (SNOTEL). The HydraProbe outputs both the real and imaginary parts of the complex permittivity. Considering that additional soil information may be obtained from the complex dielectric permittivity (Kellens et al., 2005), it comes as a surprise that not more effort is being invested to fully capitalize on such measurements. Recent studies aimed at obtaining dielectric spectra from the frequency domain have applied both open-ended as well as electrode-based probes using high-end as well as low-cost vector network analyzers (González-Teruel et al., 2022; Szyplowska et al., 2019). These advances provide more accurate means to determine SM and other soil properties (e.g., clay content and mineralogy) from spectral permittivity. Another impedance SM probe that operates at 100 MHz, but does not output complex permittivity, is the WET150 sensor (Delta-T Devices Ltd., Cambridge, UK) depicted in Fig. 2B.

Accurate EM-based determination of SM is feasible because of the large disparity between the dielectric permittivities of water (i.e., 80), solid soil constituents (i.e., about 4), and air (i.e., 1). The most accurate EM sensors generally operate at higher frequencies (~ 1 GHz) and measure travel time. This, in most instances, does not require soil specific calibration because soil permittivities at these higher frequencies are less susceptible to alteration from electrical conductivity, temperature and relaxation processes associated with high clay or organic matter contents (Szyplowska et al., 2019). For time-domain measurements, the electromagnetic signal travel time (t) is proportional to the relative permittivity (K_r) of the soil through which it travels:

$$t = \frac{2l\sqrt{K_r}}{c} \quad (3)$$

where l is the electrode length and c is the speed of light (3×10^8 m s⁻¹). Once the travel time is measured, K_r is computed to obtain a relationship with the volumetric moisture content (θ_v). A general volume-based mixing model (Jones et al., 2002; Roth et al., 1990) may be applied to infer θ_v :

$$\theta_v = \frac{K_r^\beta - (1 - \varphi)K_s^\beta - \varphi K_a^\beta}{K_w^\beta - K_a^\beta} \quad (4)$$

where φ is the soil's porosity and subscripts s , a and w refer to permittivities of solids (minerals), air, and water, respectively. The exponent β represents the geometry (layering) of the soil with values ranging between -1 and 1 , where $\beta = 0.5$ is applied for an isotropic mixture. Recently, GHz frequency TDR probes (Fig. 2C and D) such as the Digital True TDR-305 N sensor (Acclima, Inc., Meridian, ID, USA), and the SoilVUE™10 profile sensor (Campbell Scientific, Inc., Logan, UT, USA) have been developed using low-cost components, making them competitively priced relative to lower frequency EM sensors (e.g., HydraProbe and WET150).

All EM sensor measurements experience restricted applicability at high salinity levels due to signal attenuation. Severe attenuation of the EM signal may alter or prevent water content determination altogether due to very saline or clayey soil conditions.

Fig. 2 Commercial electromagnetic water content sensors. (A) HydraProbe (Stevens Water Monitoring Systems, Inc., Portland, OR, USA), (B) WET150 sensor (Delta-T Devices Ltd., Cambridge, UK), (C) Digital True TDR-305 N sensor (Acclima, Inc., Meridian, ID, USA), (D) SoilVUE™10 profile sensor (Campbell Scientific, Inc., Logan, UT, USA), and (E) Drill and Drop SM sensor (Sentek Sensor Technologies, Stepney, AUS). Sensor sizes are scaled to fit side by side—the actual lengths vary.

Furthermore, soil specific calibrations are more likely to be required in soils with high clay or organic matter (OM) contents. Permittivity of drier soils with an abundance of 2:1 clay minerals (i.e., large surface area) is more susceptible to temperature fluctuations caused by the transition of bound water to a higher permittivity free water state. Permittivity is commonly lower in OM rich soils with large specific surface areas when compared with mineral soils at the same θ_v . A further limitation of EM sensors is the determination of the total water content of frozen soils due to the low permittivity of ice (Jagdhuber et al., 2014).

In recent years, borehole or downhole sensors have been developed to determine the profile SM along the length of the sensors. These sensors include the SoilVUE™10 profile sensor (Campbell Scientific, Inc., Logan, UT, USA), and the Drill and Drop SM sensor (Sentek Sensor Technologies, Stepney, AUS) depicted in Fig. 2D and E. The SoilVUE™10 sensor is available in 0.55 or 1.05 m lengths and outputs volumetric water content θ_v for 0.05, 0.1, 0.2, 0.3, 0.4, and 0.5 m depths—the longer version additionally provides θ_v for 0.6, 0.75, and 1.0 m depths. The Drill and Drop sensor is available in lengths from 0.3 to 1.2 m and outputs θ_v every 0.1 m with the option of an integrated Bluetooth antenna that enables data readout with a mobile phone.

The Serial Digital Interface 1200 baud (SDI-12) communication protocol continues to gain popularity for environmental sensors and instruments given the capability to easily multiplex dozens of sensors from a single digital datalogger port. Sensor addressing may use single digit numbers and both upper- and lower-case letters, allowing more than 60 addresses per port on a given data logging device. Most EM sensors support SDI-12 communication.

Neutron scattering

Portable neutron probes (NP) were first deployed for measuring soil moisture (SM) in the 1950s. The concept behind the neutron scattering method is founded on the propensity of hydrogen atoms to thermalize (slow down) high-energy (2–4 MeV) neutrons emitted from a radioactive source to approach the characteristic speed of particles at ambient temperature with a corresponding energy of approximately 0.03 eV. A neutron probe is typically comprised of a radioactive neutron source (e.g., americium-241 and beryllium) and a detector (Fig. 3) to determine the flux of thermalized neutrons that form a cloud of nearly constant density near the probe. Neutrons lose various quantities of energy when colliding with different atoms. The highest energy loss is because of collisions with atoms of comparable mass, such as hydrogen. Because the quantity of hydrogen in the soil is mainly dependent on water content, a calibration equation relating the number of detected slow neutrons and soil water content can be established. To prevent entanglement with plant roots or the borehole wall, the radioactive source is commonly lowered into the soil to the desired measurement depth via an access tube (Fig. 3) made of PVC or aluminum. For accurate SM measurements calibration for each soil type and access tube material is essential. The measurement volume (sphere of influence) of a NP depends on the water content and chemical composition of the soil as well as on the strength of the radioactive source (Fig. 3). In general, reliable SM measurements can only be obtained below a depth of about 0.2 m, because close to the soil surface some of the neutrons escape into the atmosphere. To allow SM estimation closer to the soil surface, correction factors may be established, or the probe geometry modified (Hanna and Siam, 1980). Further details about the theoretical and practical aspects of the neutron scattering method are available in Sadeghi et al. (2018).

Fig. 3 Sketch of a neutron probe.

Cosmic-ray neutron probe

The cosmic-ray neutron probe (CRNP) (Fig. 4) estimates the area-averaged soil moisture (SM) by counting the neutrons within the topsoil and air that are generated by cosmic rays (Zreda et al., 2008). Similar to the standard NP, a calibration function can be established to relate the change in the number of low-energy neutrons to the change of water content. A theoretical calibration function that relates the volumetric water content (θ_v) and the relative neutron count (N/N_0) has been developed by Desilets et al. (2010):

$$\theta_v(N) = \frac{0.0808}{\left(\frac{N}{N_0}\right) - 0.372} - 0.115 \quad (5)$$

where N is the neutron count rate (count h^{-1}) normalized to a reference atmospheric pressure and solar activity level, and N_0 is the count rate (count h^{-1}) over dry soil under the same reference conditions. A detailed description of the cosmic-ray technique is provided in Zreda et al. (2012) and Andreasen et al. (2017). Because cosmic rays propagate further in thin air, the extent of the lateral measurement footprint (up to 300 m in diameter) is inversely proportional to the vapor pressure of the atmosphere. The vertical penetration depth depends on the SM content and ranges from about 15 cm in wet soils to approximately 70 cm in dry soils (Zreda et al., 2008).

A limitation of the CRNP is its sensitivity to hydrogen sources other than SM (e.g., atmospheric water vapor, organic matter, or root biomass), which may yield θ_v values that surpass soil porosity. This is why additional adjustments are necessary to eliminate the artifacts related to these additional sources as, for example, shown in Bogena et al. (2013).

Ground penetrating radar

The ground penetrating radar (GPR) is a geophysical proximal sensing technique applicable for two- and three-dimensional mapping of soil moisture (SM). A transmitter antenna emits high frequency (50 MHz to 3.6 GHz) electromagnetic (EM) waves

Fig. 4 CRNP setup in a creosote dominated shrubland in the Santa Rita Mountains southeast of Tucson, Arizona, USA. Photo credit: Dr. Trenton Franz, University of Nebraska, Lincoln.

into the subsurface. The waves are refracted, reflected, and scattered and sensed by a single or multiple receiver antennas (Klotzsche et al., 2018). Similar to time domain reflectometry (TDR), the travel time of the EM wave between the transmitter and receiver antennas is measured and the bulk dielectric permittivity of the soil (ϵ_b) that is mainly governed by the volumetric water content (θ_v) is inferred. Dielectric mixing models (e.g., Eq. 4) (Anbazhagan et al., 2020) or empirical relationships are then used to convert ϵ_b to θ_v . The most widely applied empirical relationship between θ_v and ϵ_b was developed for mineral soils by Topp et al. (1980):

$$\theta_v = -5.3 \times 10^{-2} + 2.92 \times 10^{-2} \epsilon_b - 5.55 \times 10^{-4} \epsilon_b^2 + 4.3 \times 10^{-6} \epsilon_b^3 \quad (6)$$

Three widely used GPR configurations include on-ground (surface), off-ground, and cross-borehole measurements (Klotzsche et al., 2018). On-ground measurements are commonly conducted with GPR systems that contain the transmitter and receiver antennas at a fixed separation distance and are pushed or dragged across the land surface (Fig. 5).

Off-ground GPR systems are installed at a distinct elevation above the land surface and usually mounted on a mobile platform (e.g., ATV) that drives over the soil surface. Minet et al. (2012) demonstrated that field scale θ_v can be mapped with full-waveform inversion. Some challenges associated with off-ground GPR are the sensitivity to surface roughness and the shallower measurement depth when compared to on-ground GPR. In the cross-borehole configuration, the transmitter and receiver antennas are located in two parallel boreholes. The measured two-dimensional EM wave velocity distribution between the boreholes is recorded and converted to ϵ_b and consequently to θ_v .

Electromagnetic induction

Electromagnetic induction (EMI) proximal sensing is based on the strong correlation between the soil water content (θ_v) and the measured apparent soil electrical conductivity (EC_a) (Carroll and Oliver, 2005; Moghadas et al., 2010; Doolittle and Brevik, 2014). Electromagnetic induction enables mapping of depth-averaged EC_a at high spatial resolution. To convert the EC_a maps to θ_v , a calibration based on independently measured θ_v at strategically selected locations is required (Corwin and Lesch, 2003). An EMI sensor emits an electromagnetic (EM) field from a transmitter coil. The emitted EM field induces weak eddy current loops into the conducting soil that in turn generate a secondary electromagnetic field that differs in amplitude and phase from the primary field. The primary and secondary fields are sensed with a receiver coil and converted to EC_a (dS m⁻¹). In addition to the spacing between the transmitter and receiver coils, the distance between the coils and land surface, and the coil orientation (i.e., parallel, or perpendicular to the land surface), the magnitude of amplitude and phase differences between the primary and secondary EM fields depends on soil properties including θ_v , the concentration and types of ions in solution, the quantity and

Fig. 6 EC_a mapping in Buckeye, Arizona, USA, to evaluate the salt leaching efficacy of border irrigation in an alfalfa field. EC_a maps were generated prior (A) and after (B) border irrigation. (C) The DUALEM-1S EMI sensor (Dualem Inc., Milton, Ontario, Canada) is carried over the field in 4-m spaced parallel trajectories. A GPS unit is used to georeference EC_a measurements.

mineralogy of clay constituents, and the phase and temperature of the soil water. Fig. 6 depicts mapping of EC_a with a DUALEM-1S EMI sensor in Buckeye, Arizona, USA, to evaluate the salt leaching efficacy of border irrigation in an alfalfa field.

Nuclear magnetic resonance imaging

Nuclear magnetic resonance imaging (NMRI) is based on the sensitivity of the NMRI signal intensity (echo) to soil water content (θ_v). Paetzold et al. (1985) was among the first to apply NMRI for soil moisture monitoring. The most fundamental MRI principle for θ_v determination is spin-echo imaging (Merz et al., 2016), in which an echo is created by a 180° radio-frequency pulse following an initial 90° radio frequency pulse. The echo intensity depends on the proton density, which is proportional to the water content of the soil and the relaxation times. Merz et al. (2014) tested three MRI methods for estimating near surface θ_v using the relationship:

Fig. 7 Temporal near-surface θ_v profile evolution measured with different NMRI techniques. Reproduced from Merz S, Pohlmeier A, Vanderborght J, van Dusschoten D, and Vereecken H (2014) Moisture profiles of the upper soil layer during evaporation monitored by NMR. *Water Resources Research*, 50(6): 5184–5195. doi:10.1002/2013WR014809.

$$\theta_{MR} = (\theta_{a,MR} - \theta_{r,MR}) / (1 - \theta_{r,MR}) \quad (7)$$

with $\theta_{a,MR} = M(0, r) / M(0, r)_{sat}$ where $M(0, r)$ and $M(0, r)_{sat}$ denote the signal amplitude at partial and initial saturation, respectively. $\theta_{r,MR}$ is the relative magnetic resonance (MR) signal when the soil is at residual water content (i.e., dry). Fig. 7 depicts high resolution near-surface moisture profiles for medium sand monitored over time during evaporative drying with three NMRI methods (Merz et al., 2014).

Microwave radiometry

Passive microwave systems, known as radiometers, operate at long wavelengths (L-band; 1–2 GHz or 30–15 cm) and can be applied to measure thermal radiation and brightness temperature of soil and plant surfaces. Proximal L-band radiometers are commonly mounted on fixed towers or mobile platforms. The Eidgenössische Technische Hochschule (ETH) Zürich L-band Radiometer (ELBARA) is an example for a passive system that was built by the University of Bern in collaboration with ETH to measure the brightness temperature of the land surface for soil moisture retrieval at frequencies from 1.4 to 1.427 GHz (Mätzler et al., 2003). The ELBARA radiometer underwent several alterations. The ELBARA II is a newer generation of passive radiometers. It operates at 1.4 GHz and has been developed for ground calibration and validation of the Soil Moisture and Ocean Salinity (SMOS) satellite soil moisture retrieval algorithms (Schwank et al., 2010). The ELBARA-III radiometer was applied to measure freeze-thaw dynamics and soil moisture on the Tibetan Plateau (Zheng et al., 2019). Another passive radiometer is the L-band Combined Radar and Radiometer (ComRAD) simulator (O'Neill et al., 2007), which was developed by NASA's Goddard Space Flight Center (GSFC) in collaboration with George Washington University to test and refine the soil moisture retrieval algorithms for the Soil Moisture Active Passive (SMAP) satellite under controlled conditions (Srivastava et al., 2015) and to develop new radiative transfer soil moisture retrieval algorithms for vegetated terrain and small tree canopies (Kurum et al., 2011).

Summary

In many regions, the Earth's surface experiences extreme spatiotemporal variations in soil moisture that are amplified by the changing global climate. To provide water and food security for the rapidly growing human population and to aid with the conservation and sensible use of water resources, accurate spatiotemporal information about the soil moisture (SM) status is of essence. Proximal sensing techniques provide an exceedingly powerful means for characterization, monitoring, and mapping of soil moisture from the pedon to watershed scales. This chapter provides an overview of contemporary state-of-the-art proximal SM estimation methods that include electromagnetic soil moisture sensors for pedon scale measurements and geophysical techniques (i.e., GPR, EMI mapping, and NMRI) as well as the cosmic-ray neutron probe (CRNP) and passive microwave radiometry for larger scales.

Abstract

The land surface temperature (LST) governs the radiative energy budget of the Earth's surface and thus is one of the main input variables for land-surface models aimed at the estimation of soil moisture and evapotranspiration, monitoring of drought conditions and crop development, mitigation of urban heat islands, quantifying soil, vegetation, and whole ecosystem response to climate change, simulating hydrological processes, and forecasting of extreme climate events (i.e., drought, wildfires, and flooding). Because the LST affects a wide range of physical, chemical, and biological soil processes from the local to the global scales, and because of its significant spatiotemporal variations, advanced methods for measurement of the LST are of essence. Proximal sensing techniques based on thermal infrared imaging or passive microwaves are powerful means for LST determination. In this Chapter we present state-of-the-art proximal LST sensing techniques, discuss the underlying theories and algorithms, and provide examples for the application of LST information.

Key points

- State-of-the-art proximal sensing methods for land surface temperature (LST) are presented.
- The underlying theories and algorithms for LST proximal sensing are discussed.
- Examples for the application of LST information are provided.

Introduction

The Global Climate Observing System's (GCOS) Terrestrial Observation Panel for Climate (TOPC) designates the land surface temperature (LST) as an Essential Climate Variable (ECV) that is central to understand and predict climate evolution, assess risks, guide mitigation and adaptation measures, and to enable the attribution of climate events to their underlying causes. The LST drives the outgoing longwave radiation and turbulent heat fluxes at the interface between the land and atmosphere (Hulley et al., 2019), and thus is regularly used as input variable for land-surface models. The LST also influences soil microbial activity and controls soil respiration, chemical reactions, and nutrient uptake by plants (Couradeau et al., 2016). Because of the highly heterogeneous land surface that is comprised of different soil types, soil moisture regimes, vegetation covers, and topographies, the LST varies substantially in space and with time. Adequate characterization and quantification of the LST distribution and its variability necessitates measurements with detailed spatio-temporal sampling. Because of the complexity of the LST dynamics, ground-based point measurements do not provide data that are representative for large areas. Hence, indirect proximal and remote sensing techniques that measure the surface radiation energy (radiance) in the thermal infrared region of the electromagnetic spectrum or utilize passive microwaves are essential for time efficient, non-destructive, and continuous measurement of surface temperature over expansive areas of land.

Thermal radiation

Solar radiation, the amount of energy emitted by the sun as electromagnetic waves, is the primary source of energy for all processes occurring on Earth's surface. Part of the solar radiant energy is absorbed by the land surface and transformed to kinetic energy,

Table 1 Average emissivity for different land surfaces for the long-wave infrared region (8 to 14 μm).

Type of Material	Average Emissivity (ϵ)
Healthy vegetation	0.96–0.99
Dry vegetation	0.88–0.94
Wood	0.93–0.94
Sand	0.90
Dry soil	0.92
Wet soil	0.95–0.98
Water	0.98–0.99
Snow	0.98–0.99

thereby increasing surface temperature, while part is reflected back into the atmosphere. If the surface temperature exceeds absolute zero (i.e., -273.15°C), thermal radiation (i.e., electromagnetic energy) is emitted from the surface. The thermal radiation increases with increasing object temperature, allowing for measurement of surface temperature by quantifying the surface-emitted energy, notably in the infrared region (1 to 14 μm) of the electromagnetic spectrum.

The Stefan-Boltzmann law describes the flux of radiation energy (J_r) [W m^{-2}] received at the outer surface of the atmosphere as a function of temperature and emissivity. It implies that all objects continuously emit energy proportional to the fourth power of their surface temperature:

$$J_r = \sigma \epsilon T^4 \quad (1)$$

where σ is the Stefan-Boltzmann constant ($5.670374 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$), ϵ is the emissivity [–] (varies between 0 and 1), and T is surface temperature [K]. Emissivity is defined as the ratio of the radiation energy of the object (grey body) to that of a blackbody at the same temperature, signifying the object's capacity for emitting thermal radiation. A blackbody is an idealized physical body that absorbs all incident electromagnetic radiation. For a perfect emitter or blackbody, ϵ is equal to 1, but ϵ commonly ranges between 0.8 and 1.0 for most land surfaces (Lillesand et al., 2015) (Table 1). The ϵ is mainly governed by the water content of the soil and vegetation cover, where higher water content indicates higher emissivity (Mira et al., 2010). The emissivity of healthy vegetation in the long-wave thermal infrared region exceeds 0.95 due to the high emissivity of water in leaf tissue, whereas it is below 0.95 for dry vegetation (Table 1). The land surface of natural and managed ecosystems usually comprises a mixture of soil and vegetation, both exhibiting different ϵ values. The resultant surface emissivity is a combination of soil and vegetation emissivity based on the fractions of the two surfaces. In agroecosystems, emissivity exhibits significant temporal variations due to the rapidly changing plant cover during the growth period.

The relationship between surface temperature and radiated energy of a perfect emitter, assuming that the surface emits equally in all directions, is described by Planck's law (Taylor, 1987):

$$E_r(\lambda, T) = \frac{c_1}{\lambda^5} \left[\exp\left(\frac{c_2}{\lambda T}\right) - 1 \right]^{-1} \quad (2)$$

where E_r is the spectral radiance [$\text{W m}^{-2} \mu\text{m}^{-1}$] at wavelength λ [μm] and temperature T [K] with $c_1 = 3.7417 \times 10^8 \text{ W } \mu\text{m}^4 \text{ m}^{-2}$ and $c_2 = 1.4388 \times 10^4 \mu\text{m K}$. In Eq. (1), ϵ varies with wavelength for different surfaces (e.g., soils, rocks, vegetation), hence, Eq. (2) needs to be modified to include the wavelength dependance of ϵ . Eq. (2) is inverted to solve for the surface temperature (T) of an actual surface. The relationship for E_r (Eq. (2)) as a function of surface temperature and wavelength is depicted in Fig. 1. It demonstrates that the radiative energy increases with increasing temperature, the peak of the spectrum of emitted energy shifts to shorter wavelengths as temperature increases, and the energy emitted at shorter wavelengths increases more rapidly with temperature than the energy emitted at longer wavelengths.

The basics of proximal LST sensing

Brightness temperature

The brightness temperature T_b , also referred to as radiance temperature, has been frequently used for ground- and remote sensing-based thermal infrared measurements. When the emitted radiation from a surface equals that of a blackbody, the temperature of the blackbody is defined as the T_b of the surface. It should be noted that T_b has the dimensions of temperature but lacks the physical meaning of temperature. This means that there is a difference between T_b and LST that is dependent on the amount of incident atmospheric radiation. The difference may be significant when the atmospheric emission is high, particularly in the long-wave infrared region (8 to 14 μm). Nonetheless, T_b can be used to estimate LST, when there is a single thermal infrared

Fig. 1 The spectra of emitted radiance at various wavelengths and temperatures calculated with Eq. (2). The spectral radiance for low temperature surfaces peaks at longer wavelengths.

wavelength or channel. T_b is defined as the temperature at which a back body ($\varepsilon = 1$) in thermal equilibrium with its surrounding would emit the sensed measured temperature. It is obtained from inversion of the *Planck* equation (Eq. 2):

$$T_b = \frac{C_2}{\lambda \ln \left(\frac{C_1}{E_r(\lambda, T) \lambda^5} + 1 \right)} \quad (3)$$

For proximal and remote sensing imaging systems, λ is the central wavelength of the image channel for sensors with one or several broad thermal infrared channels. The LST is obtained by substituting Eq. (2) back into Eq. (3) and solving for T .

Factors affecting the LST

The LST is influenced by land surface and atmospheric conditions. It is well documented that the LST measured with thermal infrared imaging systems may significantly deviate from the ambient air temperature. The magnitude of the deviation varies depending on the time of day and surface conditions. For example, the difference between air temperature and LST in the middle of the day is usually larger than the difference in the morning and throughout the night. There is still a lag time between the daily maximum air temperature and the daily maximum LST. Because water has a high specific heat capacity, the LST fluctuations are smaller for moist surfaces (e.g., well-watered soil and fresh vegetation) than for dry surfaces. The size and concentration of aerosols and gases (e.g., CO_2 , H_2O) in the atmosphere may also affect LST measurements due to absorption of surface-emitted radiance, which results in underestimation of the LST.

Due to their different thermal conductivities and specific heat capacities, soil and vegetation exhibit varying temperatures. Therefore, it is critical to record soil and plant temperatures separately and identify the factors affecting soil and plant temperature variations. The amount of water in soil can affect vegetation temperature, resulting in a large difference between canopy temperature and ambient temperature above the canopy. Due to large evaporative cooling under well-watered conditions, the canopy temperature is cooler than the air temperature above the canopy. Dry soil and water-stress conditions cause the canopy temperature to exceed the ambient air temperature. Canopy temperature measurements with a proximal thermal infrared sensor may be applied for the detection of plant water stress.

It is also important to measure LST variations in space and with time. The spatial scale can affect the magnitude of the LST. At a small scale, such as a few square meters, temperature fluctuates due to heterogeneity (variability) of surface properties including soil texture, water content, and plant attributes. The fluctuations decrease with increasing footprint. In addition, the temperature of soil constituents such as fine and coarse particles, stones, organic matter vary due to difference in their thermal properties (i.e., thermal conductivity and specific heat capacity). For such conditions, an effective (average) temperature can be considered based on the fraction of each component. Periodic LST variations may cause large temperature gradients that drive soil heat flow. While the LST is not a true representation of soil temperature, not even for the upper few centimeters of the soil profile, it substantially impacts a soil's temperature regime that regulates various physical, chemical, and biological processes.

The magnitude of the LST measured with a thermal infrared camera may be additionally affected by the spatial camera resolution, the distance between the land surface and the camera, and the surface reflectivity. For a surface with high reflectivity in the thermal infrared region, the surface temperature measured with a thermal camera is a composite of the radiation from the surface of interest and the reflected thermal emission of surrounding objects that are either colder or hotter than the surface. The larger the distance between the camera and the surface, the coarser the spatial measurement resolution. For example, in a thermal image of a distant plant, the temperature of leaves, branches, and soil may be averaged into a single pixel that is inaccurate for any of

the three individual objects. Increased relative humidity in the atmosphere can attenuate the radiated energy from the object, reducing the amount of energy detected by the thermal camera (Still et al., 2019). When thermal infrared sensors are applied, measurements need to be conducted under stable conditions to exclude as many potential impacting factors as possible. These factors include the time of day, the sensor's view angle, and the spatial resolution.

Periodic variations in soil surface temperature

Soil temperature variation is characterized by periodic changes (diurnal and seasonal) that occur in response to the inherent periodicity of the atmospheric conditions that control energy inputs to the soil surface. Meteorological controls such as cloudiness, warm and cold fronts, wind speed, and precipitation disrupt diurnal and seasonal cycles and affect the soil thermal regime. A sinusoidal function can be used to quantify the diurnal effects on soil temperature regime, defined as:

$$T(z, t) = \bar{T} + A_0 e^{-\frac{z}{d}} \sin \left[\omega(t - 8) - \frac{z}{d} \right] \quad (4)$$

where z is the soil depth, t is time, $\bar{T}$ is the average temperature at the soil surface, A_0 is the amplitude of surface temperature fluctuation (i.e., the average of the minimum and maximum temperatures), d is the characteristic damping depth defined as the depth at which the amplitude A_z decreases to the fraction $1/e$ of the surface amplitude (A_0), ω is the angular frequency ($\omega = 2\pi/P$), P is the period of oscillation (e.g., P equals 365 days or 12 months), and the 8 constant is an offset in hours to the sine function to obtain maximum soil surface temperature at 2:00 PM consistent with many field measurements. The offset value may be slightly adjusted in accordance with in situ measured temperatures to achieve optimal agreement. The damping depth is defined as:

$$d = \left[\frac{2D_H}{\omega} \right]^{0.5} = \left[\frac{PD_H}{\pi} \right]^{0.5} \quad (5)$$

where D_H denotes the soil thermal diffusivity, which can be determined using soil temperature measurements taken at two separate times and depths.

$$D_H = \frac{\pi(Z_1 - Z_2)^2}{P \left[\ln \left(\frac{A_1}{A_2} \right) \right]^2} \quad (6)$$

where A_1 and A_2 are the amplitudes of temperature fluctuations for depths z_1 and z_2 (i.e., $A_1 = A_0 e^{-\frac{z_1}{d}}$ and $A_2 = A_0 e^{-\frac{z_2}{d}}$). The estimated D_H from Eq. (6) may differ due to violations of the assumptions used to derive Eq. (6). For example, if the soil is heterogeneous with depth, the measured temperature may not be well represented by a sine function.

Proximal thermal infrared sensing of LST

The physical basis of thermal infrared sensors is linked to the fact that any grey object with a temperature above absolute zero (-273.15 K) emits infrared radiation at an infrared wavelength that is dependent on the object temperature (Fig. 1). For environmental objects, radiation commonly peaks in the long-wave infrared region (8 to 14 μm).

A Thermal Infrared (TIR) camera measures the surface temperature of an object from the generated output voltage while considering the influence of the temperatures of ambient air and adjacent objects. Fig. 2 depicts the components of surface radiation together with the effect of ambient sources on the temperature detected by a TIR camera. Assuming that the received total radiation energy from a surface ($E_{r,total}$) generates an output voltage/signal (V_{cam}) that is proportional to the power input to the camera, the total signal of the camera ($V_{cam,total}$) can be calculated as the sum of emissions from the surface ($E_{r,sur}$), reflected emissions from ambient sources ($E_{r,refl}$), and the emission from the atmosphere ($E_{r,atm}$):

$$E_{r,total} = \varepsilon \tau E_{r,obj} + (1 - \varepsilon) \tau E_{r,refl} + (1 - \tau) E_{r,atm} \quad (7)$$

where ε is the surface emissivity $[-]$, $1 - \varepsilon$ is the reflectance of the surface $[-]$, and $1 - \tau$ is the emittance of the atmosphere $[-]$. The total camera output voltage can be derived by multiplying each component with a constant c and substituting cE_r with the corresponding camera signal (V_{cam}):

$$V_{cam,total} = \varepsilon \tau V_{cam,sur} + (1 - \varepsilon) \tau V_{cam,refl} + (1 - \tau) V_{cam,atm} \quad (8)$$

where $V_{cam,sur}$ is the calculated camera output voltage for a surface of temperature T_{sur} , $V_{cam,total}$ is the total camera output voltage for the actual conditions, $V_{cam,refl}$ is the theoretical camera output voltage for surface surrounding sources with temperature T_{refl} according to the calibration, and $V_{cam,atm}$ is the theoretical camera output for ambient atmosphere with temperature T_{atm} . Rearranging Eq. (8) and solving for $V_{cam,sur}$ yields:

$$V_{cam,sur} = \frac{1}{\varepsilon \tau} V_{cam,total} - \frac{1 - \varepsilon}{\varepsilon} V_{cam,refl} - \frac{1 - \tau}{\varepsilon \tau} V_{cam,atm} \quad (9)$$

Eq. (9) is the general equation used for TIR cameras for measuring surface temperature.

Fig. 2 Schematic depicting the effect of surrounding surfaces and atmosphere on the total radiation energy detected for an object with a TIR camera.

Handheld TIR cameras

Over the last decade, portable thermal infrared sensors have gained popularity for rapid temperature measurements in a variety of fields including environmental and agricultural sciences due to their affordability, ease of use, and ability to adjust the view field to a specific surface. In agriculture, a handheld TIR camera measures the energy radiated by the soil and plant surfaces and converts the energy received at each detector pixel to a 14- or 16-bit digital number. The raw values are transformed to temperature values via sensor-specific coefficients that are derived from the underlying physics.

Because a thermal sensor is sensitive to ambient infrared radiation, further calibration is beneficial for obtaining accurate data. To compensate for the effect of the environment, the camera requires several parameters such as emissivity, which may be obtained from tabulated values (Table 1), reflected apparent temperature, distance between the surface and the camera lens, air relative humidity, and air temperature (Maguire et al., 2021). The surface emissivity of agricultural fields changes with time due to plant growth, which should be considered for LST measurements. Optical indices such as the normalized difference vegetation index (NDVI) can be used to determine surface emissivity of vegetated areas (Brunsell and Gillies, 2002).

There are various types of handheld TIR cameras. The accuracy and temperature measurement range vary depending upon camera model. For example, a FLIR TG167 camera that operates in the 8 to 14 μm spectral range with a field of view of 19.3° can typically measure temperatures ranging from -25 to 380 °C with an accuracy of ± 1.5 °C. Fig. 3 shows an example for measurements with a FLIR TG167 camera for sorghum leaves at different dates that represent well-watered (low temperature) and water-stressed (high temperature) conditions. It is possible to detect temperature of a dry and wet soil, because of the different heat conductivities and specific heat capacities under wet and dry conditions.

It should be noted that under natural light conditions the temperature of the plant canopy is a combination of sunlit and shaded temperatures. Depending upon the height and structure of the plant canopy, the contribution of the shaded portions to total canopy temperature can be significant. Most of the literature only considers the sunlit temperature to study plant response to environmental conditions. This is because the surface temperature of sunlit canopy is known to better represent the plant conditions, for example, for water stress detection. Two approaches are commonly used to consider the shadow effects including removing shaded pixels from thermal images or using a de-shadow algorithm to correct the temperature of shaded pixels based on the temperature of sunlit pixels. Fig. 4 depicts temperature differences between sunlit and shaded portions of a corn plant (Taghvaeian et al., 2013).

Stationary TIR sensors

Over the last decade, thermal infrared imaging technology has advanced significantly, and manufacturers are now able to supply a variety of state-of-the-art TIR sensors for different temperature ranges. These include laboratory and field systems for a variety of

Fig. 3 Temperature ($^{\circ}\text{C}$) and emissivity (ϵ) values of energy sorghum leaves measured with a FLIR TG167 handheld TIR camera at three different dates, in Maricopa, AZ. The cursor represents the measured leaf area.

Reproduced from Taghvaeian S, Chavez JL, Altenhofen J, Trout T and DeJonge K (2013) Remote sensing for evaluating crop water stress at field scale using infrared thermography: Potential and limitations. *Hydrology Days* doi: 10.25675/10217/201030.

applications. A thermal infrared imaging system measures the spatial distribution of surface temperature with high spatial resolution, allowing the pixels of interest to be selected for detailed analysis. For example, analysis can be limited to a portion of a full image corresponding to specific leaves of a particular plant or the soil between plants. Fig. 5 depicts a mm-scale temperature image for soil and sorghum captured with a TIR sensor mounted on a field robotic scanner (TERRA-REF, <https://terraref.org>). It is obvious that the dry soil pixels exhibit higher temperature ($\sim 320\text{ K}$) than plant pixels ($\sim 304\text{ K}$).

Microwave radiometry

Passive microwave systems, known as radiometers, operate at long wavelengths (L-band; 1–2 GHz or 15–30 cm) and can be applied to measure thermal radiation and brightness temperature (T_b) of soil and plant surfaces. At horizontal or vertical polarizations, the radiance emitted by the soil and plant canopy surfaces is a linear function of their temperature (T_s) and reflectivity (R_s). The brightness temperature measured by a radiometer oriented toward the surface is obtained from:

$$T_b = (1 - R_s)T_s + R_s T_{sky} \quad (10)$$

where $(1 - R_s)T_s$ is the upwelling brightness temperature above the surface, and T_{sky} is the downwelling sky radiation. The value of T_{sky} is determined by a radiometer oriented toward the sky.

Proximal L-band radiometers are commonly mounted on fixed towers or mobile platforms. The Eidgenössische Technische Hochschule (ETH) Zürich L-band Radiometer (ELBARA) is an example for a passive system that was built by the University of Bern in collaboration with ETH to measure the brightness temperature of the land surface for soil moisture retrieval at frequencies from 1.4 to 1.427 GHz (Mätzler et al., 2003). The radiometer is composed of a dual-mode conical horn antenna mounted on a stationary tower or the back of a truck 4–17 m above the surface. Fig. 6 shows the first generation ELBARA radiometer positioned over a plot at an experimental site in Switzerland (Mätzler et al., 2003). The footprint of the radiometer is dependent on the projection of the antenna's sensitive cone (i.e., the view angle θ), the measurement configuration defined by the observation angle φ relative to nadir, and the radiometer elevation above the land surface. The radiometer is capable of high-resolution temporal measurements of T_b in

Fig. 5 A true color composite image (left) and associated TIR image with a pixel size of $2.6 \times 2.6 \text{ mm}^2$ captured with a FLIR SC615 camera across a field planted with energy sorghum in Maricopa, AZ.

Fig. 6 ELBARA Radiometer mounted on a tower at a test site in Switzerland. θ and φ are the view and observation angles, respectively. Reproduced from Mätzler C, Weber D, Wüthrich M, Schneeberger K, Stamm C, Wydler H and Flüher H (2003) ELBARA, the ETH L-band radiometer for soil-moisture research. In: *Proceedings of International Geoscience and Remote Sensing Symposium (IGARSS)*, IEEE, Toulouse, France, pp. 3058–3060.

the order of magnitude of seconds. However, multi-angular measurements (e.g., $20 < \varphi < 60$) may limit the temporal resolution due to the time required to direct the antenna at various elevation angles and the measurement integration time. The ELBARA radiometer is equipped with internal cold (273 K) and hot (338 K) loads for onsite calibration of collected data.

The ELBARA radiometer underwent several alterations. The ELBARA II is a newer generation of passive radiometers. It operates at 1.4 GHz and has been developed for ground calibration and validation of the Soil Moisture and Ocean Salinity (SMOS) satellite soil moisture retrieval algorithms (Schwank et al., 2010). ELBARA II has been deployed in several ground campaigns in Germany, Spain, Finland, and France. The brightness temperature is obtained from the radiometer raw data through an internal calibration (Eq. 11). The calibration is conducted by periodically switching between different radiometer internal reference noise sources fed to the radiometer microwave assembly, while recording the voltage responses at the output of the power detector assembly.

$$T_b = \frac{T_{RM,in} - (1 - t_{FC})T_{FC}}{t_{FC}} \quad (11)$$

where $T_{RM,in}$ is the noise temperature at the radiometer input port for H and V polarizations, which can be expressed as:

$$T_{RM,in} = \frac{U - U_{ACS}}{U_{RS} - U_{ACS}} (T_{RS} - T_{ACS}) + T_{ACS} \quad (12)$$

where T_{ACS} and T_{RS} are the noise temperatures of internal active cold sources (ACS) and resistive noise source (RS) that yield the reference response voltages U_{ACS} and U_{RS} , respectively, U is the response voltage measured by the radiometer antenna, t_{FC} and T_{FC} are transmissivity and temperature of the lossy feed cable (FC) (t_{FC} is less than 1). As Eq. (11) indicates, T_b measured by the antenna is slightly smaller than $T_{RM,in}$ due to noise added by the lossy feed cable.

The ELBARA-III radiometer was applied to measure freeze-thaw dynamics and soil moisture on the Tibetan Plateau (Zheng et al., 2019).

Another passive radiometer is the L-band Combined Radar and Radiometer (ComRAD) simulator (O'Neill et al., 2007), which was developed by NASA's Goddard Space Flight Center (GSFC) in collaboration with George Washington University to test and refine the soil moisture retrieval algorithms for the Soil Moisture Active Passive (SMAP) satellite under controlled conditions (Srivastava et al., 2015) and to develop new radiative transfer soil moisture retrieval algorithms for vegetated terrain and small tree canopies (Kurum et al., 2011). The ComRAD consists of a quad-polarized radar (1.25 GHz) and a dual-polarized radiometer (1.4 GHz) that share a 1.22 m parabolic dish antenna with a 12 degrees field of view. The antenna is mounted on a 19 m hydraulic boom truck for field deployment. Prior to measurements, the radiometer is calibrated with cold sky and ambient microwave absorber targets.

The soil characteristics (e.g., surface roughness) and canopy structure may affect T_b measurements for both horizontal and vertical polarizations. Multangular brightness temperature measurements are beneficial for separating the effect of dense vegetation cover on soil brightness temperature measurements, as dense vegetation significantly attenuates microwave signals, resulting in large volume scattering. Multangular measurements can enhance the accuracy of soil moisture retrievals over dense vegetated areas (Gherboudj et al., 2011).

Application of LST measurements

Besides for the parametrization of land-surface models, LST measurements are used in numerous applications in agriculture and environmental science.

TIR measurements are used in agriculture for detection of plant heat and drought stress and for irrigation scheduling. Plant temperature has long been recognized as a sensitive indicator of plant water stress (Jackson et al., 1981). The principle is based on the detection of changes in leaf temperature in the presence of a root zone soil water deficit. When the relative humidity of the ambient air is low (i.e., increased evaporative gradient) and the root zone is dry, the water potential in the plant decreases. As a result, the plant stomata close, which leads to a decrease in energy dissipation and an increase in plant temperature (Buckly, 2019). The difference between air and leaf temperature can provide an indicator for plant water stress. For example, the crop water stress index (CWSI) and the normalized relative canopy temperature (NRCT) (Jackson et al., 1981) are two commonly applied indices for drought stress detection in agriculture. Previous studies show that the CWSI is strongly correlated to stomatal conductance, leaf water potential, leaf transpiration rate, available soil water, leaf CO_2 exchange rate, and crop yield (Nielsen and Anderson, 1989; Irmak et al., 2000). NRCT is defined as:

$$NRCT = \frac{T_c - T_{min}}{T_{max} - T_{min}} \quad (13)$$

where T_c is the actual canopy infrared temperature, T_{min} and T_{max} are the lowest and highest temperatures that can be either measured in the field (Elsayed et al., 2015) or calculated with theoretical models with known input parameters (Moran et al., 1994). T_{min} and T_{max} can be also considered as the wet and dry bulb temperatures determined from the air temperature and the vapor pressure deficit (Jackson et al., 1981). The equation for CWSI contains similar parameters as in Eq. (13). Both the NRCT and CWSI range from 0 to 1, with higher values indicating greater water stress. To map water-stressed crops and separate plant and soil

Fig. 7 Color (left) and LST (right) images of a furrow irrigated onion field. The LST [°C] was measured with a FLIR handheld camera. Reproduced from Taghvaeian S, Chavez JL, Altenhofen J, Trout T and DeJonge K (2013) Remote sensing for evaluating crop water stress at field scale using infrared thermography: Potential and limitations. *Hydrology Days* doi: [10.25675/10217/201030](https://doi.org/10.25675/10217/201030).

temperatures for irrigation scheduling, TIR measurements may be integrated with a GPS. Fig. 7 depicts the LST of a field planted with onion (Taghvaeian et al., 2013).

Surface temperature measurements are also regularly used to estimate soil moisture content. Due to the sensitivity of the surface temperature to soil and plant water content variations, TIR and optical observations may be integrated into a triangle or trapezoid model to estimate soil moisture (Moran et al., 1994). This approach has been frequently applied for large scale soil moisture estimation from satellite observations. It has the potential to be applied in conjunction with high spatial resolution imaging systems at the field scale. As discussed above, L-band radiometer brightness temperature observations are commonly used to estimate surface soil moisture and vegetation water content using either a dielectric mixing model (Srivastava et al., 2015) or a radiative transfer model (Kurum et al., 2011). A dry bare soil typically exhibits a large brightness temperature that is approximately 150 K higher than the temperature under saturated conditions. The characteristics of the soil and plant surface such as surface roughness and plant canopy structure (e.g., height and leaf area index) may influence the radiometer brightness temperature measurements.

Another area of application of LST is the estimation of evapotranspiration. When combined with vegetation indices (e.g., the normalized difference vegetation index, NDVI) measured with proximal visible and near-infrared sensors, soil and plant surface temperatures can be used for estimating actual evapotranspiration. This approach has been successfully applied at large scales using satellite thermal infrared and optical observations (Price, 1990; Carlson et al., 1994). Previous studies show that the evaporative fraction and relative soil moisture are linearly related to the surface temperature gradient Λ (Sandholt et al., 2002; Carlson, 2007) defined as:

$$\Lambda = \frac{ET_a}{ET_0} = \frac{LST_{dry} - LST}{LST_{dry} - LST_{wet}} \quad (14)$$

$$\Lambda = \frac{\theta}{\theta_s} = \frac{LST_{dry} - LST}{LST_{dry} - LST_{wet}} \quad (15)$$

where ET_0 and ET_a are the potential and actual evapotranspiration, respectively, θ and θ_s are the actual and saturated soil moisture content, respectively, LST is the land surface temperature, and subscripts 'dry' and 'wet' denote the highest and lowest surface temperatures determined via plotting NDVI versus LST for a wide range of soil and plant surface temperature and vegetation conditions. In addition, thermal imaging provides potential means for quantification of plant stomatal conductance from the temperature difference between the air and the plant leaf (Leinonen et al., 2006).

Other LST measurement applications include detection of leaf frost injury symptoms (Stegner et al., 2019) and plant pathogens (Stoll et al., 2008) as well as the assessment of aboveground biomass (Winterhalter et al., 2011) and root biomass (Lopes and Reynolds, 2010).

Abstract

Evapotranspiration (*ET*) is a key component of the water and energy cycles. In-depth knowledge about *ET* is of essence for a plethora of applications that include estimation of crop water consumption, irrigation scheduling and water resources management, modeling of hydrologic processes, forecasting of drought conditions, and monitoring of ecosystem response to climate change. Various proximal sensing methods may be applied in conjunction with the land surface energy balance or the terrestrial water balance to estimate *ET* at the local scale. In this chapter, we review state-of-the-art proximal *ET* sensing techniques along with their underlying theories.

Key points

- The importance of evapotranspiration (*ET*) is reviewed along with the governing soil and atmospheric variables.
- *ET* estimation by state-of-the-art proximal sensing techniques is described together with the terrestrial water and land surface energy balances.

Introduction

Evapotranspiration (*ET*) encompasses all processes related to water movement from the land surface to the atmosphere via evaporation and transpiration. *ET* consists of water evaporation into the atmosphere from the soil surface and water bodies, evaporation from the capillary fringe of the groundwater table, and transpiration — the movement of water from the soil to the atmosphere via plants. Transpiration occurs when plants take up liquid water from the soil and release water vapor into the air via their stomata. *ET* links the water, energy, and carbon cycles, hence, significantly affecting land surface-atmosphere interactions. *ET* regulates the balance of water and energy of the Earth's biosphere, hydrosphere, and atmosphere, especially in arid and semiarid ecosystems, where it may account for nearly the entire surface water budget (Fisher et al., 2017; Oki and Kanae, 2006; Morillas et al., 2013). Warming of the land and atmosphere causes fundamental changes in *ET*, because warmer air holds more water vapor evaporated from the soil surface and transpired by plants. This leads to shifts in the patterns and seasonality of precipitation and soil moisture, which modifies the balance between the water cycle components and may result in extreme weather events such as floods, droughts, wildfires, and landslides. For example, in arid and semiarid areas drought conditions are exacerbated during periods of low precipitation. Accurate estimation of *ET* is essential for the determination of agricultural and ecosystem water use, drought detection, quantification of land-atmosphere feedbacks, assessment of the anthropogenic impact on the water cycle and surface energy budget, and for validation and improvement of the parameterization of land surface models (Purdy et al., 2018). Typically, *ET* is estimated from the water or energy balance. Proximal sensing techniques, including eddy covariance and scintillometer methods, provide powerful means for indirect measurements of land surface and atmospheric variables, which may be integrated with surface energy balance to provide robust spatiotemporal *ET* estimates at the local scale.

The energy balance of the land surface and evapotranspiration

The land surface net radiation (R_n), the difference between the incoming and outgoing radiation, drives evapotranspiration (ET) and the air and soil heat fluxes as well as other processes with lower energy consumption (e.g., photosynthesis). The energy balance of the land surface is formulated as:

$$R_n = \lambda ET + H + G \quad (1)$$

where λET is the latent heat flux (W m^{-2}) with λ representing the latent heat of vaporization (2.449 MJ kg^{-1} or 585 cal g^{-1}), H is the sensible heat flux (W m^{-2}), i.e., the energy utilized to heat the air, and G is the soil heat flux (W m^{-2}), i.e., the energy used to heat the soil. The magnitude of R_n is determined by several factors, including albedo, latitude, and terrain characteristics (e.g., slope and aspect). Under wet surface conditions (i.e., wet soil and well-watered plants), most of R_n is consumed by ET . Fig. 1 depicts the components of the surface energy balance and their direction relative to the land surface.

The terrestrial water balance and evapotranspiration

The basic equation describing the water balance, which is based on the conservation of the mass of water, is given as:

$$P + I = ET + DR + RO - \Delta W \quad (2)$$

where P is precipitation, I is irrigation, ET is evapotranspiration, DR is drainage and deep percolation, RO is surface runoff, and ΔW is the change in the soil water storage (water depletion). All components of the water balance are commonly expressed in length units. W is defined as the equivalent depth of water (D_e) stored in a soil profile under consideration over a specific time period (i.e., $\Delta W = W_{t_1} - W_{t_2}$). D_e is the depth of the soil profile multiplied with the average volumetric soil water content of the profile. All components of the water balance are associated with a specific time interval (t_1 to t_2), and all water additions to the soil profile are assigned a positive sign, whereas all outputs have a negative sign. Water balance calculations may be applied to areas ranging in size from small plots (e.g., backyard garden) to watershed and global scales.

Factors that control evapotranspiration

Evaporation (E) and transpiration (T) occur simultaneously and are difficult to discern. From a physics perspective, E is the transformation of liquid water to water vapor. This process requires energy that is supplied by R_n and, to a lesser extent, by the ambient air temperature. The difference between the water vapor pressure at the evaporating surface and that of the surrounding air drives E . As E progresses, the air surrounding the evaporating surface becomes progressively saturated with water molecules, and E will eventually cease if the saturated air is not transferred to the atmosphere. Under such conditions, the replacement of humid air with dryer air is primarily determined by wind speed. Transpiration (T) is the process by which soil water is taken up by plant roots, transported through the plant xylem, and evaporated at the surface of mesophyll cells in the plant leaves before exiting through stomata. The soil water status and atmospheric water vapor content (i.e., relative humidity) affect stomata opening and closing. During precipitation or irrigation events, the plant canopy intercepts and absorbs a portion of the water. Precipitation or irrigation

Fig. 1 Schematic of the surface energy balance components. T_{low} and T_{high} refer to soil temperature.

that is not intercepted is called throughfall and water that reaches the ground via trunks and stems is referred to as stemflow. A portion of the intercepted water evaporates at rates determined by the prevailing atmospheric conditions and the physiology of plants. In temperate humid regions, evaporation of intercepted water is an important component of the water balance. Forests commonly exhibit greater interception losses than grasslands. This is because of the greater aerodynamic roughness of the forest canopy that results in a more efficient transfer of water vapor away from the evaporating canopy surfaces.

Variations in atmospheric and soil conditions affect the rate of evapotranspiration. In general, factors such as atmospheric demand, soil water availability, soil texture and structure, and plant physiological aspects affect the rate of ET . Net radiation, air temperature, relative humidity, and wind speed are the major atmospheric parameters that control the atmospheric demand. Reference or potential evapotranspiration expresses the effect of the atmosphere on water loss. The reference evapotranspiration represents the water loss from a fully vegetated surface covered with grass or alfalfa.

The soil moisture (SM) status along with the ability of the soil to transmit water to the plant roots are significant determinants of the ET rate. SM controls the partitioning of the total available energy (i.e., R_n) into sensible (H) and latent (λET) heat fluxes at the land surface and determines near-surface ambient air conditions (relative humidity). LeMone et al. (2007) demonstrate that the SM content may significantly impact the magnitude of sensible and latent heat fluxes. ET is mainly influenced by the SM deficit and the soil type. Saturated soil conditions cause oxygen deficiency that limits root water uptake. The transpiration rate is affected by plant physiology and characteristics such as development stage, canopy roughness, canopy height, and rooting depth. Furthermore, agricultural management practices may influence the transpiration rate, especially under water stress. Nutrient status, soil salinity, the presence of impeding soil layers, plant diseases, and pests are additional factors to be considered when estimating ET , as they all may limit plant growth and thus reduce the rate of ET .

Energy balance-based proximal sensing of evapotranspiration

The eddy covariance method

The eddy covariance (EC) method is frequently applied in agriculture, hydrology, ecosystem science, and industry. EC systems measure atmospheric fluxes of H_2O , CO_2 , sensible heat (H), and latent heat (λET) that are transferred as eddies of varying size caused by turbulence within the atmospheric boundary layer. Mathematically, the EC method is based on the covariance between vertical transfer velocity measurements, the concentration of the quantity of interest, and the upward and downward air movements (Burba, 2013). As depicted in Fig. 2, at a single location on an EC system and for a single instant of time ($t = 1$), eddy #1 transports an air parcel with mass c_1 and velocity v_1 downward. At $t = 2$, eddy #2 propels an air parcel of mass c_2 upward with velocity v_2 . Because each air parcel possesses unique characteristics, the flux of interest is determined from the concentration, temperature, and humidity, among other variables. By measuring these characteristics along with the velocity of the vertical air movement, the vertical upward or downward fluxes of water vapor and gas concentrations can be determined.

Rapid fluctuating turbulent conditions pose challenges to EC measurements. The upward and downward motions and the number of molecules must be measured at high frequency, which requires sophisticated instrumentation that is capable of measuring small concentration fluctuations, densities, and temperatures with high accuracy. The EC method has distinct advantages over other ET estimation techniques that include: (1) direct measurements of sensible heat (H), and latent heat (λET) fluxes; (2) minimal disturbance of the region of interest; (3) spatially averaged measurements over large areas; and (4) automation capability for continuous long-term measurements.

The EC method determines the latent heat flux (λET) from the covariance between fluctuations in instantaneous vertical wind speed and water vapor density according to:

$$\lambda ET \text{ (W m}^{-2}\text{)} = \lambda \overline{\delta v \delta \rho_v} \quad (3)$$

where λ is the latent heat of vaporization (2260 J g^{-1}), $\overline{\delta v}$ is the mean fluctuation of the vertical wind speed (m s^{-1}) measured over a specific time period (e.g., 30 min), and $\overline{\delta \rho_v}$ is the mean fluctuation of water vapor density (g m^{-3}) for the same time period.

Fig. 2 Sketch illustrating the measurement principle of the eddy covariance method. Reproduced from Burba G (2013) *Eddy Covariance Method for Scientific, Industrial, Agricultural, and Regulatory Applications: A Field Book on Measuring Ecosystem Gas Exchange and Areal Emission Rates*. LI-COR Biosciences: Lincoln, Nebraska. <https://doi.org/10.13140/RG.2.1.4247.8561>.

The sensible heat flux (H) is a consequence of the direct transfer of heat from the land surface to the atmosphere due to convection and conduction processes as well as the temperature gradient between the land surface and the atmosphere. H may be calculated as:

$$H \text{ (W m}^{-2}\text{)} = \rho_a C_p \overline{\delta v} \overline{\delta T_a} \quad (4)$$

where ρ_a is the air density (g m^{-3}), C_p is the specific heat capacity of air at constant pressure ($\text{J g}^{-1} \text{ } ^\circ\text{C}^{-1}$), $\overline{\delta v}$ is the mean fluctuation of the vertical wind speed (m s^{-1}) measured over a specific time period (e.g., 30 min), and $\overline{\delta T_a}$ is the mean fluctuation of the air temperature ($^\circ\text{C}$) for the same time period.

The EC method is based on the following assumptions: (1) measurements at a specific point represent an upwind area; (2) fluxes are turbulent; (3) the terrain is horizontal and uniform; (4) measurements are conducted within the boundary layer and inside the constant flux layer; (5) air density fluctuations are negligible; and (6) instruments are capable of capturing small changes at extremely high frequencies. The extent to which some of these assumptions are valid depends on the selection of an appropriate site, the experimental design, and the atmospheric conditions.

Fig. 3 depicts a typical EC system consisting of a 3-D sonic anemometer for measuring wind speed and direction. The anemometer is commonly integrated with a gas analyzer for CO_2 and H_2O vapor concentration measurements. Wind speed and direction and CO_2 and H_2O vapor concentrations need to be measured at high frequency (i.e., 5–20 Hz). The system may further comprise of air temperature and relative humidity sensors, a net radiometer as well as soil moisture sensors and heat flux plates vertically distributed along the soil profile to measure additional soil and atmospheric variables. All measured data are automatically recorded with a data acquisition system.

The major variables measured with a basic EC system are listed in Table 1. The analysis of EC measurements is not trivial because numerous corrections are required. Burba (2013) provides an extensive review of the EC method including data analysis.

Fig. 4 shows diurnal variations of λET , H , and R_n for lettuce and wheat for mid- and end-growth stages. In the middle of the growth season, when soil water is not limited, the majority of R_n is expended by λET .

The EC method is the technique of choice for measuring surface fluxes at AmeriFlux (<https://ameriflux.lbl.gov/>) and FLUXNET (<https://fluxnet.org/>) sites. AmeriFlux is a network of more than 470 registered flux tower sites distributed across North, South, and Central America. It was established to quantify water, energy, and carbon fluxes to determine the role of the terrestrial biosphere in global climate change. FLUXNET is an international “network of networks,” connecting regional networks of earth system scientists, who use the EC method to measure the cycling of carbon, water, and energy between the biosphere and atmosphere to better understand ecosystem functioning, and to detect trends in climate, greenhouse gases, and air pollution.

Table 1 A list of major variables measured with an eddy covariance system.

Variable	Units
H ₂ O flux	$\text{g m}^{-2} \text{s}^{-1}$
CO ₂ flux	$\text{mg m}^{-2} \text{s}^{-1}$
H ₂ O concentration	$\text{g m}^{-2} \text{s}^{-1}$
CO ₂ concentration	$\text{mg m}^{-2} \text{s}^{-1}$
Friction velocity	m s^{-1}
Shear stress	$\text{kg m}^{-1} \text{s}^{-2}$
Latent heat flux	W m^{-2}
Sensible heat flux	W m^{-2}
Mean wind speed in x, y, z directions	m s^{-1}
Covariance of H ₂ O and mean wind speed in x, y, z directions	$\text{g m}^{-2} \text{s}^{-1}$
Covariance of C ₂ O and mean wind speed in x, y, z directions	$\text{mg m}^{-2} \text{s}^{-1}$

**Fig. 4** Diurnal variations of surface energy balance components for mid-season and end of season growth stages of lettuce and wheat planted in Maricopa and Yuma, Arizona, USA, in 2018, respectively.

The scintillometer method

There are different types of scintillometers, namely large aperture scintillometers (LAS) that operate at near-infrared (NIR) wavelengths ($\sim 850 \text{ nm}$), and microwave scintillometers that operate at wavelengths of about 2 mm. The LAS is designed to measure the sensible heat flux (H) over path lengths from 100 m up to 5 km. When combined with a microwave scintillometer (Fig. 5), both H and the latent heat flux (λET) can be measured directly. If the LAS is used on its own, the area-averaged λET can be determined as a residual of the surface energy balance (Eq. 1) when net radiation (R_n) and the soil heat flux (G) are additionally measured with suitable instrumentation (e.g., net radiometer and heat flux plates) (Meijninger et al., 2002).

Fig. 5 Operation principle of a scintillometer (left). A Kipp & Zonen LAS MkII Scintillometer (OTT HydroMet B.V., Delft, The Netherlands) combined with an RPG-MWSC-160 microwave scintillometer (RPG Radiometer Physics GmbH Meckenheim, Germany) for direct measurement of H and λET (right).

Scintillometers measure fluctuations in turbulent intensity and display them as a path-averaged structure parameter of the air refractive index C_n^2 . For example, a LAS transmitter emits a horizontal near-infrared (NIR) beam, which is captured by the receiver that analyzes the resulting beam fluctuations caused by density and turbulence-induced atmospheric scintillations. C_n^2 is related to the temperature structure parameter C_T^2 , air pressure P (Pa), air temperature T (K), and the Bowen ratio (β):

$$C_T^2 = C_n^2 \left(\frac{T^2}{\gamma P} \right)^2 \left(1 + \frac{0.03}{\beta} \right)^{-2} \quad (5)$$

where C_T^2 and C_n^2 are expressed in units of $K^2 m^{-2/3}$, and $m^{-2/3}$, respectively, and γ is the air refractive index parameter ($-0.78 \times 10^{-6} K Pa^{-1}$). β can be determined from eddy covariance measurements, or iteratively when the difference between R_n and G is known (Solignac et al., 2009; Ezzahar et al., 2009). H is iteratively derived from C_T^2 and wind speed data based on the semiempirical Monin-Obukhov similarity theory (MOST):

$$H (W m^{-2}) = \rho_a C_p u^* T^* \quad (6)$$

where C_p is the specific heat of air ($J kg^{-1}$), ρ_a is the air density ($kg m^{-3}$), u^* is the friction velocity ($m s^{-1}$), and T^* is an air temperature scale. Details about the MOST analysis are provided in Foken (2006) and McAneney et al. (1995).

Scintillometers offer some advantages over the eddy covariance method, including average flux observations over longer distances, which are sounder for the estimation of total crop water consumption in agriculture, and require less complex setups, maintenance, and data processing. There are also some limitations associated with the scintillometer method that include effects of meteorological constraints on long-term measurements (e.g., precipitation, poor visibility, and weak turbulence), methodological constraints (e.g., signal saturation and inner-scale signal dependence), and sensitivity to vibrations of the mounting platform. Terrain characteristics, such as surface topography, type of land cover, and non-uniformity in vegetation height, may also affect the measurement accuracy.

Water balance-based proximal sensing of evapotranspiration

The evapotranspiration (ET) for agricultural fields can be calculated over a specific time period (t) as the residual of the water balance:

$$ET(t) = \sum_{i=1}^t (P + I + \Delta W - RO - DR) \quad (7)$$

where ET is evapotranspiration, P is precipitation, I is irrigation, ΔW is the change in the soil water storage (water depletion with), RO is surface runoff, and DR is drainage and deep percolation. It is common to express the components of the water balance in length units.

The accuracy of water balance-based ET estimates depends on the measurement errors associated with the methods used to determine the water balance components. P and I can be measured accurately with rain gauges and flow meters, respectively. RO is commonly considered negligible for flat surfaces (e.g., agricultural fields), and DR can be determined from the difference between P or I and ΔW short after precipitation or irrigation events.

The ΔW can be measured with state-of-the-art electromagnetic (EM) proximal soil moisture sensors that operate based on the travel time, capacitance, or impedance measurement principles. Commonly applied EM sensors include the HydraProbe (Stevens Water Monitoring Systems Inc., Portland, OR, USA), the WET150 sensor (Delta-T Devices Ltd., Cambridge, UK), the Digital True TDR-305N sensor (Acclima, Inc., Meridian, ID, USA), the SoilVUE™10 sensor (Campbell Scientific, Inc., Logan, UT, USA),

and the Drill and Drop SM sensor (Sentek Sensor Technologies, Stepney, AUS). While the HydraProbe, WET150, and Digital True TDR-305N sensors are applicable for point measurements with several sensors typically distributed vertically along the soil profile, the SoilVUE™10 and Drill and Drop probes are a new generation of profiling sensors that are available in various lengths up to 1.2 m.

ΔW can be also measured with geophysical proximal sensing methods such as ground penetrating radar (GPR) or electromagnetic induction (EMI). The GPR is applicable for two- and three-dimensional mapping of soil moisture. A transmitter antenna emits high frequency (50 MHz to 3.6 GHz) electromagnetic waves into the subsurface. The waves are refracted, reflected, and scattered and sensed by a single or multiple receiver antennas (Klotzsche et al., 2018). Similar to time domain reflectometry (TDR), the travel time of the EM wave between the transmitter and receiver antennas is measured and the bulk dielectric permittivity of the soil (ϵ_b) that is mainly governed by the volumetric soil water content (θ_v) is inferred. Dielectric mixing models (Anbazhagan et al., 2020) or empirical relationships (e.g., Topp et al., 1980) are then used to convert ϵ_b to θ_v , and subsequently to calculate ΔW .

Electromagnetic induction (EMI) proximal sensing is based on the strong correlation between the soil water content (θ_v) and the measured apparent soil electrical conductivity (EC_a) (Carroll and Oliver, 2005; Doolittle and Brevik, 2014). EMI enables mapping of depth-averaged EC_a at high spatial resolution. To convert the EC_a maps to θ_v , a calibration based on independently measured θ_v at strategically selected locations is required (Corwin and Lesch, 2003). An EMI sensor emits an electromagnetic (EM) field from a transmitter coil. The emitted EM field induces weak eddy current loops into the conducting soil that in turn generate a secondary electromagnetic field that differs in amplitude and phase from the primary field. The primary and secondary fields are sensed with a receiver coil and converted to EC_a (dS m⁻¹). In addition to the spacing between the transmitter and receiver coils, the distance between the coils and land surface, and the coil orientation (i.e., parallel, or perpendicular to the land surface), the magnitude of amplitude and phase differences between the primary and secondary EM fields depends on soil properties including θ_v , the concentration and types of ions in solution, the quantity and mineralogy of clay constituents, and the phase and temperature of the soil water.

Summary

Evapotranspiration (ET) is a major component of the water and energy cycles. It reflects the intricate interactions between soil, vegetation, and weather patterns, which are being altered by the changing global climate. To conserve and sensibly use water resources in Earth's water-starved regions, accurate spatiotemporal information about ET is crucial. Proximal sensing techniques provide powerful means for quantification of ET at the local scale. This chapter provides an overview of state-of-the-art proximal ET sensing techniques including the eddy covariance and scintillometer methods, electromagnetic sensors, ground penetrating radar and electromagnetic induction, which are applied in conjunction with either the land surface energy balance or the terrestrial water balance.

Abstract

Soil moisture is an essential climate variable and knowledge about its state and dynamics is vital for numerous applications, from agricultural drought monitoring to studying land–atmosphere interactions. Remote sensing instruments mounted on satellites are currently our only way to obtain frequent observations of global soil moisture patterns. This chapter provides: (i) an overview of state-of-the-art remote sensing technology that can be used for space-borne soil moisture monitoring, (ii) an account on physical and empirical retrieval models used to generate remotely sensed soil moisture products, and (iii) an outlook into current and future cutting-edge developments.

Key points

- Remote sensing instruments suitable for soil moisture retrieval and their characteristics are introduced.
- Soil moisture retrieval theory and retrieval algorithms are described.
- Common soil moisture missions and products are outlined.
- An overview of common soil moisture remote sensing applications is provided.
- An outlook into current and future developments is presented.

Introduction

In situ sensing techniques, most commonly using dielectric probes of a few centimeters length, are considered to be the most accurate source for soil moisture information. However, in situ soil moisture sensors sample only the water content within a few cubic centimeters of soil. Since soil moisture changes rapidly in both space and time due to its strong dependence on soil texture, topography, and meteorological drivers, ground measurements are very localized and can seldom be used as a proxy for the soil moisture conditions of a larger area (a single point-scale sensor may indeed capture the temporal dynamics that result from large-scale rainfall events and area-wide post-rain dry-downs, yet the absolute magnitude of these readings is only accurate for the small soil volume in which the sensor is placed) (Brocca et al., 2012). Nevertheless, there are many applications, such as agricultural drought monitoring or climate modeling, for which the knowledge of the soil water distribution over very large areas (that is, from

the field to the continental scale) is vitally important (Dorigo et al., 2017). But because in situ measurements are so limited in their spatial representativeness and due to the fact that the global land surface is vast and in many regions hard to access, the use of proximal soil moisture sensing techniques for these applications is not feasible.

Instead, such applications rely almost exclusively on remote sensing, which is the topic of this chapter. Remote sensing refers to the process of acquiring information about an object from a distance without physical contact. The information-carrying media, in this case, are electromagnetic waves, and the sensors used to detect these waves can be placed anywhere from fairly close to the object of interest (ground-based remote sensing) all the way up to space (satellite- or space-borne remote sensing). The latter is of most interest for soil moisture monitoring as modern Earth observing satellites can provide complete scans of almost the entire Earth's surface within just 2–3 days. The downside of measuring soil moisture from space, however, is that these measurements have a rather coarse resolution (an individual measurement represents the average soil moisture conditions of an area that is typically in the order of hundreds to thousands of square kilometers, but for many applications this is not a significant limitation, as we shall see).

This chapter will provide a broad overview of the field of soil moisture remote sensing. Section “Platforms and instruments” discusses the technology used for soil moisture remote sensing and its most important characteristics, and section “Soil moisture retrieval” elaborates on the methods used to turn measurements of electromagnetic waves into soil moisture estimates. Section “Common missions and products” provides an overview of the most common state-of-the-art soil moisture remote sensing products, and section “Soil moisture remote sensing applications” outlines typical applications that rely on remotely sensed soil moisture. Lastly, section “Conclusion and outlook” gives an outlook on novel soil moisture remote sensing research and developments that can be expected in the years to come.

Platforms and instruments

A remote sensing platform is an object or vehicle that carries one or more remote sensing instruments. We can distinguish roughly between ground-based platforms (these can be measurement towers, buildings, rover vehicles, etc.), airborne platforms (i.e., airplanes and UAVs), and spaceborne platforms (i.e., satellites). The remote sensing instruments mounted on such a platform are devices that measure electromagnetic waves. Although some methods exist to retrieve soil moisture information from measurements in the visible and infrared regions of the electromagnetic spectrum, microwave observations are considered to be the most suited for soil moisture retrieval because the dielectric properties of water are distinctly different from those of almost everything else found in natural soils (Ulaby et al., 2014), as will be elaborated later in section “Soil moisture retrieval” (a second advantage of microwave measurements is that they can be taken day and night and are largely unaffected by clouds and atmospheric conditions). For this reason, virtually all modern remote sensing soil moisture products are retrieved from microwave observations, and so this chapter will be limited to this domain. The following sections will provide an overview of the different remote sensing platforms that are used for soil moisture retrieval—or for the development of soil moisture retrieval algorithms—and discuss the various characteristics of remote sensing instruments and how these determine how much information about soil water content we can extract from their measurements.

Tower and airborne systems

As mentioned above, most remotely sensed soil moisture data sets are commonly retrieved from microwave instruments mounted on satellites because they can provide frequent quasi-global soil moisture maps. Although microwave instruments can be (and are) mounted on ground-based measurement towers and airplanes, these measurements are of little practical use for soil moisture retrieval because towers cover only small areas that can be sampled with proximal sensors (which are cheaper and more accurate) and airplane flights cannot be made frequently and repeatedly, and also cover only relatively small regions. Tower-based and airborne microwave measurements are, however, vitally important for the calibration and validation of satellite instruments as well as for the development of the radiative transfer theory used for soil moisture retrieval (Montzka et al., 2020).

Calibration and validation refers to the process of comparing the raw microwave radiance measurements from the satellites to those made by instruments on a tower or on an airplane. This serves to quantify (and, where possible, account for) systematic and random errors in the satellite measurements (hereinafter referred to as biases and uncertainties, respectively). In general, this is done in a controlled laboratory environment, but because this is, for obvious reasons, not possible for space-borne instruments, we have to rely on comparisons with well-calibrated ground-based equipment (i.e., tower and airborne measurements). From these comparisons, we obtain quantitative estimates of biases and uncertainties in the satellite radiance measurements that allow us to make educated guesses about the accuracy that we can expect from soil moisture retrievals made from these measurements (soil moisture retrieval accuracy will, of course, not only be determined by radiance measurement errors, but also by the ability of the retrieval algorithm to convert these radiance measurements into soil moisture estimates; see section “Soil moisture retrieval”) (Merchant et al., 2017).

Most importantly, tower and airplane measurements allow us to create reasonably controlled field environments to study the interactions between microwaves and the land surface, that is, how exactly electromagnetic waves interact with the soil and the vegetation that covers it depending on soil texture, topography, vegetation types, and, most importantly, water content. Such experiments are utilized to derive theoretical forward models to predict the behavior of microwaves given some land surface conditions, which can then be inverted to retrieve soil moisture from actual microwave measurements, as will be discussed in detail in section “Soil moisture retrieval”.

Space-borne systems

Thousands of satellite missions are orbiting the Earth. The ones suited for soil moisture monitoring fall into the category of Earth observation satellites. These are launched into a wide range of orbits (which determine if and how often a certain region of the Earth is revisited) and vary greatly in their instrumentation depending on their intended purpose. Since many satellites are tax-funded, their data are freely available for scientific use. This has greatly fostered the development of novel data sets beyond the initial applications planned for these satellite missions. Remotely sensed soil moisture products, for example, have been retrieved from satellites since the mid-1980s even though the first dedicated soil moisture satellite mission was launched in only 2009 (see section “Common missions and products”).

As mentioned, soil moisture retrievals are predominantly made from microwave instruments. Microwave instrument-carrying satellites can be categorized into active systems (radar systems) and passive systems (radiometers). Radar systems carry antennae that actively emit microwaves and then measure the radiation that has been reflected back by the Earth’s surface, whereas radiometers passively observe the microwave radiation that is emitted by the Earth’s surface due to its physical temperature (Ulaby et al., 2014), as illustrated in Fig. 1. Radar instruments can be further divided into real-aperture radar (or “radar”, for short) and synthetic-aperture radar (SAR). The latter combine multiple successive measurements made by a relatively small radar antenna along the flight path through sophisticated processing techniques so that each measurement appears to have been taken by a much larger synthetic antenna. The reason for doing this is that the spatial resolution of radar measurements is limited by the antenna length (at best a few meters) and the satellite altitude (typically around 700–800 km). These two parameters effectively limit the measurements of real-aperture radar systems and radiometers to a spatial resolution of about 10^2 – 50^2 km², while SAR processing can yield spatial resolutions of a few square meters, albeit with a *much* lower signal-to-noise ratio. For many applications, however, the time interval between observations and their accuracy is more important than spatial resolution, which often outweighs the benefit of the higher spatial resolution of SAR instruments (see section “Soil moisture remote sensing applications”).

The orbit of a satellite together with the antenna geometry and observation strategy determine how frequently a given location is observed (radar systems and radiometers are often designed to observe as large an area as possible whereas SAR scans often have to be focused on specific regions of interest due to technical limitations such as power supply versus consumption). Most satellite missions used for soil moisture retrieval are so-called sun-synchronous polar orbiters. This means that their orbit follows the Earth’s revolution and movement around the sun, and hence that each point on the Earth is revisited at about the same time during a day, every few days apart depending on the latitude (areas near the poles are observed more frequently than areas near the equator). Modern radar systems and radiometers have typical revisit times of about 1–3 days, whereas SAR scans can be weeks to months apart, depending on the observation mode (see section “Common missions and products”).

Instrument characteristics

Satellite-based microwave instruments have three important characteristics that influence how well they are suited for soil moisture retrieval made from these instruments (Ulaby et al., 2014). These are the microwave frequency and polarization, and the antenna incidence angle.

The microwave domain of the electromagnetic spectrum covers a frequency range from about 300 MHz to 300 GHz (about 1 mm to 1 m wavelength). Various microwave bands have been used for soil moisture retrieval (Dorigo et al., 2017) including K_a-band (0.5–1.5 mm wavelength), K_u-band (1.5–2.5 cm), X-band (2.5–3.7 cm), C-band (3.7–7.5 cm), and L-band (15–30 cm). In general, the longer the wavelength, the less the radiation is affected by vegetation covering the soil and the deeper it can penetrate into the ground, thus making it more sensitive to soil moisture. In contrast, the shorter the wavelength, the better is the spatial

Fig. 1 Schematic illustration of (A) passive remote sensing, and (B) active remote sensing. Courtesy Gabrielle De Lannoy.

resolution. Typical spatial resolutions for different frequency bands are roughly in the order of 10^2 – 25^2 km², 15^2 – 25^2 km², 20^2 – 40^2 km², 25^2 – 50^2 km², 35^2 – 50^2 km², for K_a-, K_u-, X-, C-, and L-band, respectively. The benefit of the greater soil moisture sensitivity of longer wavelengths usually outweighs the benefit of a slightly improved spatial resolution, which is the reason why most state-of-the-art soil moisture products are retrieved from C-band and L-band measurements (see section “Common missions and products”).

Microwave antennae measure radiation at a particular polarization, that is, oscillating either parallel to the Earth’s surface (horizontally polarized; H) or perpendicular to it (vertically polarized; V). Radiometers measure H or V polarized radiation (or both) emitted from the Earth’s surface itself while radar systems and SARs emit the radiation at a chosen polarization and then measure the reflected radiation either at the same polarization (co-polarized; VV or HH) or at the other respective polarization (cross-polarized; VH or HV). Vertically (co)polarized measurements have been found to be more sensitive to soil moisture than horizontally (co)polarized measurements, and co-polarized measurements are more sensitive to soil moisture than cross-polarized measurements. Nevertheless, because cross-polarized measurements are more sensitive to vegetation cover, they can potentially be used to correct for unwanted vegetation signal components in co-polarized measurements.

Lastly, microwave instruments used for soil moisture retrieval typically point at the Earth’s surface at a particular angle, referred to as the incidence angle, which can be either fixed for all measurements (e.g., at 40 degrees) or vary across the antenna swath (e.g., 25–65 degrees). Microwave measurements exhibit a strong dependence on the incidence angle due to structural land surface characteristics, in particular soil roughness and vegetation geometry. Instruments that observe at a fixed incidence angle, therefore, have the advantage that all measurements are influenced by these characteristics in the same way, which may make it easier to account for these effects in the soil moisture retrieval algorithm. On the other hand, taking measurements at a range of incidence angles provides additional degrees of freedom that may be used to derive (and hence correct for) the incidence angle relationships.

Soil moisture retrieval

A plethora of methods exists to extract the soil moisture signal from the microwave measurements made by remote sensing instruments, referred to as soil moisture retrieval. This section provides a broad overview of the key underlying principles that most existing retrieval algorithms share. In addition, we will outline state-of-the-art methods used to push the boundaries of the soil moisture information we *can* observe from space-borne microwave remote sensing. For example, how to extract root-zone soil moisture estimates from microwave measurements that are only sensitive to the soil surface (the penetration depth of these measurements into the soil is roughly in the order of the wavelength, i.e., a few centimeters depending on the microwave band, and can vary significantly in space and time because it depends on the soil structure and the soil water content) and how to resolve sub-pixel soil moisture variation within coarse resolution satellite measurements.

Physical retrieval models

Physically-based soil moisture retrieval relies on the statistical inversion of forward models that describe what the remote sensing instruments measure (microwave radiation) as a function of the land surface conditions (soil characteristics and vegetation cover). Although forward models differ for active and passive remote sensing instruments (remember that active sensors emit their own signal and measure their return reflected by the Earth’s surface, also referred to as backscatter, whereas passive sensors measure the microwave signal naturally emitted by the Earth’s surface, referred to as brightness temperature) they comprise the same two components: one that describes what happens within the soil and one that describes what happens within the vegetation covering it.

Forward modeling for active remote sensing

Active sensors measure the area-normalized change in magnitude of a microwave signal that they emitted and that has returned to the sensor after having been reflected by the Earth’s surface (Ulaby et al., 2014). This quantity is referred to as backscatter (σ^0). The backscatter depends on the geometric and the dielectric properties of the reflecting object (i.e., the Earth’s surface) and is modeled separately for the soil and for the vegetation.

Soil backscattering

The dielectric properties of the soil (expressed in terms of the dielectric constant ϵ) determine how much of an incoming microwave signal is reflected at the soil–atmosphere interface and how much penetrates into the soil or is absorbed. Since the soil is a mixture of materials (mineral components, organic components, water, and air) its dielectric properties depend on the dielectric properties of its components. Precise theoretical modeling of the soil dielectric properties at the microscale using dielectric mixing models is possible but very complex. More importantly, given the immeasurable diversity in possible soil composition and structure, purely theory-based soil dielectric models contain a multitude of parameters and variables that are impossible to determine and parameterize in practice. Therefore, semi-empirical models have been developed that mimic the behavior of these models, but only require a few variables and parameters that are known to be the most significant drivers of the soil dielectric constant and are relatively easy to obtain (Dobson et al., 1985). These are usually the microwave frequency, soil temperature, salinity, soil texture, and, of course, soil water content. As mentioned, water has a very high dielectric constant while all other soil components have a very low one. Consequently, the dielectric constant, and hence the backscatter, of the soil are predominantly determined by soil moisture (the higher the soil water content, the greater is the backscatter). The effect of soil texture influences the soil dielectric

Fig. 2 Schematic illustration of rough surface scattering. Courtesy Raphael Quast.

constant indirectly by limiting its overall dynamic range. This is because sandy soils can hold much more water per volume than soils with higher clay content. The effects of soil temperature and salinity are, for soil moisture remote sensing purposes, often considered to be negligible. The general structure of these models can be written as:

$$\varepsilon = f(f, T, S, s, c, \Theta) \quad (1)$$

where f is the microwave frequency; T is the temperature; S is the salinity; s and c are the sand and clay fraction, respectively, which, together, represent the soil texture; and Θ is the soil moisture. The most commonly used soil dielectric models are the so-called Dobson model (Dobson et al., 1985), the Mironov model (Mironov et al., 2013), and the Wang and Schmugge model (Wang and Schmugge, 1980). For a detailed presentation of their exact model structures, we refer the reader to the respective references.

While the dielectric properties of the soil affect how much of the microwave signal is reflected by the soil surface, the geometric properties of the soil, more precisely its “roughness”, determine the directionality of these reflections (recall that microwave instruments typically observe at an incidence angle that can be as much as 65 degrees). The rougher the surface, the more isotropic the soil scattering becomes, as illustrated in Fig. 2. This behavior depends on the microwave frequency: the scattering will converge to an isotropic scattering behavior as the surface roughness, expressed in terms of the surface height standard deviation and its horizontal auto-correlation length, approaches the wavelength (Ulaby et al., 2014).

Taken together, the backscattering behavior of soils is described in so-called soil backscatter models as a function of dielectric and geometric properties. The only relevant physically-based soil backscattering models worth mentioning here are the Integral Equations Method (IEM) model (Fung et al., 1992), and its extensions, the Advanced IEM (AIEM) model and the Improved IEM (I²EM) model (Ulaby et al., 2014) (the soil dielectric constant used as an input to these models, however, is typically obtained from a semi-empirical soil dielectric model rather than from a physical one; see above). Such a soil backscattering model can be expressed as:

$$\sigma_s^0 = f(\theta, \varepsilon, h_s, l) \quad (2)$$

where σ_s^0 is the soil backscatter; θ is the incidence angle; and h_s and l are the standard deviation and auto-correlation length of the surface height profile, respectively. Given the highly complex, non-linear structure of these models, we omit their lengthy presentation here and refer the reader to the respective references.

Vegetation scattering

Most global ecoregions, from rainforests through savannas to boreal forests, are covered with some form of vegetation which needs to be accounted for in the backscatter forward modeling. Physically-based forward models do this by means of radiative transfer theory. Radiative transfer models (RTMs) describe the net energy change of the microwave radiation as it passes through the vegetation both while traveling from the sensor towards the soil surface and while traveling back to the sensor after having been reflected by the soil surface (as described by the soil backscatter model). This energy change occurs due to the scattering of the microwave radiation within the vegetation structure and signal absorption. Both of these effects depend strongly on the overall biomass, the structural composition of the vegetation, and the vegetation’s water content (Ulaby et al., 2014).

It is not hard to imagine that a geometrically accurate representation of a vegetation cover and its water content distribution is, for areas as large as the satellite radar footprints, virtually impossible to build. Even though attempts have been made to do so (one example is the Michigan Microwave Canopy Scattering (MIMICS) model that describes the vegetation as a collection of dielectric cylinders, representing trunks and branches, and discs, representing leaves), nearly all vegetation scattering models that are used for remote sensing purposes use a simplified description of vegetation. The most popular such description is the so-called Water Cloud Model (WCM), which is a first-order solution to the radiative transfer equations and gets its name from (figuratively) representing the heterogeneous vegetation cover of a very large area as a homogeneous layer of water droplets (Attema and Ulaby, 1978). This simplified vegetation layer is fully characterized by only two quantities, the scattering albedo (ω) and the vegetation optical depth (τ), and models only the two most dominant components of the microwave scattering behavior, which are (i) the signal that is scattered back to the sensor by the vegetation before reaching the soil surface, and (ii) the signal that penetrates through the vegetation and is reflected back to the sensor by the soil surface. So-called interaction terms, which describe microwave radiation that has been scattered multiple times within the vegetation canopy and at the soil surface before traveling back to the sensor, are

Fig. 3 Illustration of the components modeled in (A) the τ - ω model: (1) upwelling soil emission attenuated by the vegetation canopy, (2) direct upwelling vegetation emission, and (3) downwelling vegetation emission reflected by the soil and attenuated by the canopy layer; and (B) the WCM: (1) backscatter from the soil surface, (2) backscatter from the vegetation canopy, and (3) backscatter from radiation that was reflected once from both the vegetation and the soil surface, respectively. Note that the backscatter interaction term (3) of the WCM is commonly considered negligible. Courtesy Gabrielle De Lannoy.

commonly assumed to be negligible and thus usually not modeled, even though recent research has made attempts to account for these interaction terms in soil moisture retrieval algorithms (Quast et al., 2019). The WCM can be written as:

$$\sigma^0 = \frac{3\omega}{4} \cos \theta \left(1 - e^{-\frac{2\tau}{\cos \theta}} \right) + \sigma_s^0 e^{-\frac{2\tau}{\cos \theta}} \quad (3)$$

The factor $\frac{3}{4}$ arises by assuming that the vegetation exhibits Rayleigh scattering. Alternatively, the directionality of the vegetation scattering could be described more accurately by a so-called phase function (Quast et al., 2019). The scattering components modeled in the WCM are illustrated in Fig. 3.

Forward modeling for passive remote sensing

The following sections will summarize the most relevant principles for the modeling of passive microwave signatures from the land surface. The interested reader can find a detailed and more comprehensive account on that subject matter in Wigneron et al. (2017).

Soil emission

According to Planck's law, any object with non-zero physical temperature emits radiation over the entire electromagnetic spectrum. Passive microwave sensors measure the so-called brightness temperature T_b , which is the microwave radiation at a particular frequency and polarization, and can be related to the soil's effective temperature T as:

$$T_b(\theta) = e(\theta) * T \quad (4)$$

where e is the soil emissivity, which is related to the soil reflectivity (R) as:

$$e(\theta) = 1 - R(\theta) \quad (5)$$

which is related to the soil backscatter in that it is its integral over the scattering hemisphere (Ferrazzoli et al., 1989). The soil emissivity thus holds the information about soil dielectric and geometric properties and is modeled, just as the soil backscatter, by means of a soil dielectric model and a soil roughness model. While the soil dielectric models used for emissivity modeling are largely the same as those used for modeling active microwave signatures, the passive soil moisture remote sensing community most commonly uses (semi)empirical soil roughness models such as the HQN model rather than the physical models that were outlined above for soil backscatter modeling (although the active remote sensing community has spent more effort investigating these physical soil roughness models, they are not commonly used for soil moisture retrieval from active sensors either, most likely because they are highly non-linear and virtually impossible to parameterize accurately for the large areas covered by space-borne microwave antenna footprints).

Vegetation emission and scattering

Virtually all commonly used physically-based retrieval algorithms for passive microwave observations use a zero-order solution to the radiative transfer equations, which is commonly known as the τ - ω model. Like the WCM, it is fully described by the scattering albedo and the vegetation optical depth. Similar to the WCM, it represents three components contributing to the total observed brightness temperature, which are (i) the direct upwelling vegetation emission, (ii) the downwelling vegetation emission reflected by the soil and attenuated by the canopy layer, and (iii) upwelling soil emission attenuated by the vegetation canopy, as illustrated in Fig. 3:

$$T_b = (1 - \omega) \left(1 - e^{-\frac{\tau}{\cos \theta}} \right) T_c + (1 - \omega) \left(1 - e^{-\frac{\tau}{\cos \theta}} \right) e^{-\frac{\tau}{\cos \theta}} R T_c + (1 - R) e^{-\frac{\tau}{\cos \theta}} T_g \quad (6)$$

where T_c and T_g are the effective soil and vegetation temperatures, respectively. Typically, these are assumed to be equal and modeled as a single, effective temperature T_e . Note that the brightness temperature, and hence also ω , τ , and R , are different for H and V polarizations. Although the τ - ω model does not model first- and higher-order (i.e., multiple scattering) effects, it is commonly assumed that these effects can be accounted for to a sufficient degree of accuracy if the scattering albedo and the

vegetation optical depth are calibrated as “effective parameters”, that is, by specifically calibrating them to the modeled land surface environment (Wigneron et al., 2017).

Model inversion

Physically-based backscatter and brightness temperature models are too complex to be inverted analytically. Therefore, soil moisture is retrieved from these models using non-linear optimization algorithms, which aim to minimize a cost function of the following form:

$$x = \min_x \sum_i (\gamma_i^{\text{obs}}(\mathbf{x}) - \gamma_i^{\text{mod}}(\mathbf{x}))^2 \quad (7)$$

where γ^{obs} and γ^{mod} are the observed and modeled backscatter or brightness temperature, respectively, i may refer to different polarizations, incidence angles, or other parameter values that yield degrees of freedom, and the vector $\mathbf{x}$ holds the forward model variables that are being optimized, that is, soil moisture (some algorithms not only estimate soil moisture but also other state variables such as vegetation optical depth or other related dynamic parameters). These cost functions are complex, and the retrievals are thus quite sensitive to the choice of the optimization algorithm and the initial values.

Physically-based retrieval algorithms

The sections above touched upon the basic principles for the physical modeling of active and passive microwave emission and scattering. A multitude of soil moisture retrieval algorithms has been developed based on these principles. These differ in the choices made for individual model components (e.g., soil dielectric models), auxiliary data (e.g., effective soil and canopy temperatures), simplifying assumptions (e.g., neglecting polarization dependency), and inversion algorithms (e.g., solving for soil moisture only or for both soil moisture and vegetation optical depth). A complete account of these algorithms is beyond the scope of this chapter; the interested reader is referred to Wigneron et al. (2017).

(Semi-)empirical retrieval models

While most common passive-microwave-based soil moisture products are retrieved using the physically-based retrieval algorithms described above, this is not the case for active-microwave-based products. Various empirical approaches have been proposed that fit simple non-linear functions experimentally to backscatter and the quantities anticipated to be its most dominant drivers, i.e., soil moisture, roughness, radar incidence angle, soil texture, etc. (e.g., Oh et al., 1992) or even simply between backscatter and the soil dielectric constant (Loew et al., 2006). The by far most common retrieval algorithm for active-microwave-based soil moisture retrievals is the so-called TU Wien change detection method (Wagner et al., 1999), which is also the only algorithm that has been implemented for the operational production of soil moisture products, both from real-aperture radar systems and from SAR instruments. This method retrieves soil moisture as the degree of soil saturation (Θ_s) by scaling the observed backscatter on a particular day between the historically lowest and highest observed backscatter observations (referred to as dry reference, σ_{dry}^0 , and wet reference, σ_{wet}^0), which are assumed to represent completely dry and completely saturated conditions, respectively:

$$\Theta_s = \frac{\sigma^0 - \sigma_{\text{dry}}^0}{\sigma_{\text{wet}}^0 - \sigma_{\text{dry}}^0} \quad (8)$$

This algorithm further exploits multi-incidence angle observations to correct for the seasonally varying vegetation component in the backscatter signal as part of an incidence angle normalization step (Wagner et al., 1999).

Lastly, several probabilistic and machine-learning-based approaches have been tested for both active-microwave-based and passive-microwave-based soil moisture retrieval. One such approach, based on artificial neural networks, has been implemented recently for operational near-real-time soil moisture retrieval from the SMOS satellite (Rodríguez-Fernández et al., 2015).

Root-zone soil moisture estimation

As noted earlier, microwave measurements are only sensitive to the top few centimeters of the soil. Therefore, soil moisture retrievals obtained using the methods described above also only represent the water content in this shallow surface soil layer. Many applications, however, are more interested in the water content of the plant root-zone (see section “Soil moisture remote sensing applications”). Several strategies exist to derive root-zone soil moisture estimates further from surface soil moisture retrievals. Two of these strategies are worth mentioning here.

The first is the calculation of the so-called Soil Water Index (SWI; Wagner et al., 1999) which serves as a proxy for deeper-layer soil moisture, albeit without a clear definition of the exact depth of the soil layer it represents. The SWI is calculated by applying an exponential filter to the surface soil moisture estimates, which mimics the natural infiltration process:

$$SWI(t_n) = \frac{\sum_i^n \theta(t_i) e^{\frac{t_n - t_i}{T}}}{\sum_i^n e^{\frac{t_n - t_i}{T}}} \quad (9)$$

where θ is the remotely sensed surface soil moisture retrieval, and T is the so-called characteristic time length in the unit of days, which represents infiltration duration. The larger T is, the deeper is the soil layer that the SWI represents. Although the SWI has been found to correlate well with in situ measurements of deeper layer soil moisture, a specific T value cannot be associated with an exact soil depth because water infiltration properties depend strongly on soil characteristics, topography, and climatic conditions. Nevertheless, Paulik et al. (2014) have found that T values ranging from 0 to 50 represent soil layers from 0 to 50 cm in a relatively linear fashion (although with a significant spread), which can serve as a rough “rule of thumb”.

An alternative approach for obtaining root-zone soil moisture estimates from surface soil moisture retrievals is through hydrological modeling, that is, by simulating the physical processes of plant and soil evaporation, surface runoff, infiltration, and so on. However, such an approach requires a plethora of auxiliary input data such as measurements of temperature, radiation, and humidity as well as information on soil texture, topography, and land cover. This, therefore, starts to leave the realm of remote sensing and enters the field of model-data integration. The most common way to integrate satellite surface soil moisture retrievals (or raw satellite radiance measurements) with soil hydrological modeling is through data assimilation, where the satellite data are used to update soil moisture predictions of a numerical model by “pulling them in the right direction” (Reichle et al., 2002). The most popular example for an operational root-zone soil moisture product that has been generated by integrating remote sensing observations with a global land surface model is the so-called SMAP Level-4 (L4) product (Reichle et al., 2017a,b).

High-resolution soil moisture estimation

High-resolution soil moisture products are in high demand by the user community for a variety of local and regional applications. Active microwave platforms, particularly SAR sensors, provide a direct way to obtain high-resolution soil moisture estimates. Currently, Sentinel-1C-band backscatter data are used to generate high spatial resolution (1 km) soil moisture at regional/continental scales (Bauer-Marschallinger et al., 2019). Relevant operational products have also been released by the Copernicus Global Land service. Nevertheless, soil moisture retrieval algorithms for SAR data still need to be improved to account better for the effects of vegetation, surface roughness, and incidence angle. An alternative way to obtain high spatial resolution soil moisture is to downscale existing coarse-resolution soil moisture products. High-resolution optical and infrared data, radar backscatter, or prior knowledge of soil moisture variation have been used to improve the spatial resolution of various soil moisture products. The general concept of these downscaling approaches is to fuse coarse-resolution soil moisture and fine-resolution auxiliary variables by building either statistical or physical scaling models (Fig. 4; Peng et al., 2017). Several fused high-resolution soil moisture products have been recently developed and published, such as a combined SMAP/Sentinel product (1 km/3 km), and an ASCAT/Sentinel-1 product (1 km). In addition, the integration of multi-satellite platforms offers the opportunity to produce sub-daily soil moisture products, such as the combination of Metop-A, -B, and -C satellites carrying the Advanced Scatterometer (ASCAT), and the combination of optical/thermal geostationary satellites with microwave satellites. Despite these advances, novel fusing algorithms (e.g., machine learning) and modeling frameworks (data assimilation) still need to be developed to combine multi-source data sets better to generate long-term high spatial resolution soil moisture products. Future satellite missions will even provide new capabilities to provide soil moisture at both high spatial and temporal resolutions.

Soil moisture retrieval validation

The validation of soil moisture retrievals from remote sensing observations faces a particular challenge, which is the difficulty to obtain “ground-truth” estimates of the exact soil moisture conditions within the large satellite footprints (which are in the order of hundreds of square kilometers) to compare the retrievals against. Extensive field campaigns have been carried out to obtain highly accurate soil moisture proxies at the satellite footprint scale, but these are labor and time-intensive, and can only be done infrequently and over very small areas. However, retrieval accuracy varies substantially across the globe depending on the retrieval algorithm’s ability to account for specific land surface characteristics (such as vegetation, topography, landscape heterogeneity, and so on). Consequently, field campaigns or heavily equipped in situ measurement sites will never be able to provide assessments of satellite retrieval accuracy that are representative of all relevant geographic conditions.

Fig. 4 Illustration of the downscaling of coarse-resolution soil moisture products using fine-resolution auxiliary data.

Fig. 5 Soil moisture validation protocol. Modified from Gruber A, De Lannoy G, Albergel C, Al-Yaari A, Brocca L, Calvet J-C, Colliander A, Cosh M, CrowW, Dorigo W, Draper C, Hirschi M, Kerr Y, Konings A, Lahoz W, McCol K, Montzka C, Muñoz-Sabater J, Peng J, Reichle R, Richaume P, Rüdiger C, Scanlon T, van der Schalie R, Wigneron J-P and Wagner W (2020) Validation practices for satellite soil moisture retrievals: What are (the) errors? *Remote Sensing of Environment* 244: 111806. <https://doi.org/10.1016/j.rse.2020.111806>.

The soil moisture remote sensing community has developed various strategies to tackle this issue, which are described in detail in Gruber et al. (2020). In essence, satellite soil moisture validation consists of various layers, that is, comparisons against reference data sets from different sources with varying quality and availability. These range from assessments with a few heavily-equipped ground reference sites (so-called core validation sites) that provide highly accurate estimates of accuracy yet at only a few locations worldwide, to inter-comparisons with lower-quality products that serve more as consistency checks but that can be done globally. The different characteristics of these reference data sets necessitate various pre-processing steps, such as spatial and temporal collocation or the removal of climatological differences, as illustrated in Fig. 5. For more detail about the steps involved, we refer to Gruber et al. (2020), but two vital ideas in this process are worth elaborating here.

First, the exact soil volume that a space-borne microwave instrument “sees” is more of a factitious concept rather than an actual volume due to the vast extent of the antenna footprints, which exhibit a microwave signal gradient from the center outwards, and the varying signal penetration depth. Therefore, it is difficult to obtain a reliable estimate for the absolute amount of water within an only approximately defined soil volume. But in many cases, it is sufficient to know *how much the soil moisture changes* even though the absolute amount of water is uncertain. Fortunately, soil moisture changes are not very localized. If it rains, it rains over large areas and if the sun dries out the soil, it does so over large areas. Accordingly, point measurements of single in situ stations can represent large-scale dynamics fairly accurately. Research has shown that as few as 1–5 carefully placed in situ sensors can represent satellite footprint scale soil moisture dynamics with <5% uncertainty (Brocca et al., 2012) (different locations within a satellite footprint may be more or less representative for the footprint-average soil moisture dynamics depending on the landscape and climatic conditions; locations that are more representative are commonly referred to as temporally stable locations; Vachaud et al., 1985). This allows satellite validation studies to utilize so-called sparse networks, that is, ground measurement networks with sparsely distributed in situ sensors, to assess soil moisture retrieval accuracy at least in terms of their skill in capturing temporal soil moisture

dynamics. For estimates of absolute soil moisture retrieval accuracy, the best solutions are still heavily-equipped sites or dedicated field campaigns.

The second key idea to satellite soil moisture validation that allows us to obtain spatially complete estimates of soil moisture retrieval accuracy is that one does not necessarily need a high-quality reference data set as long as one has several reference data sets whose errors are independent from each other. Specifically, a statistical method called triple collocation analysis (TCA) can estimate the individual *random* errors of three data sets x , y and z , neither of which needs to be error-free (or even highly accurate, for that matter) as:

$$\begin{aligned}\sigma_{\epsilon_x}^2 &= \sigma_x^2 - \frac{\sigma_{xy}\sigma_{xz}}{\sigma_{yz}} \\ \sigma_{\epsilon_y}^2 &= \sigma_y^2 - \frac{\sigma_{yx}\sigma_{yz}}{\sigma_{xz}} \\ \sigma_{\epsilon_z}^2 &= \sigma_z^2 - \frac{\sigma_{zx}\sigma_{zy}}{\sigma_{xy}}\end{aligned}\quad (10)$$

where σ_{ϵ_i} is the random error variance of data set i , σ_i^2 is the variance of data set i , and σ_{ij} is the covariance between data sets i and j . These individual estimates of random error variance are truly independent from those of the respective others and remain unchanged even if one or both of the other data sets are exchanged with another data source, provided that all statistical assumptions relevant to the method are respected. For a detailed description of TCA, we refer to Gruber et al. (2016). Note, however, that TCA only estimates *random* errors. There is still no method available that can accurately determine absolute biases in satellite soil moisture retrievals over larger areas.

Common missions and products

An overview of the most commonly used remotely sensed soil moisture products and information about what satellite mission/sensor they have been retrieved from, their temporal coverage and resolution, their spatial resolution, and where to access them is provided in Table 1. The following section will provide an overview of common applications for these products.

Soil moisture remote sensing applications

Satellite soil moisture products have been widely used to serve a variety of disciplines, such as hydrology, Numerical Weather Prediction (NWP), climate modeling, ecology, and agriculture (see Fig. 6; Dorigo et al., 2017). For some disciplines, the application of satellite soil moisture has become mature and widespread. For example, satellite soil moisture is widely used for the evaluation of global climate model performance and to understand land–atmosphere interactions better. Based on ASCAT and AMSR-E soil moisture products, for example, Taylor et al. (2012) demonstrated a negative feedback between soil moisture and precipitation, with afternoon rainfall being more likely to occur on dry soils across the globe. Miralles et al. (2014) found that the declining trends in global evapotranspiration and soil moisture were related to El Niño and La Niña cycles. Satellite soil moisture products, particularly ASCAT, SMOS, and SMAP, have also been used to improve NWP by assimilating them into various NWP systems (de Rosnay et al., 2020). In addition, satellite soil moisture plays an important role in a range of hydrological applications like runoff simulation, flood forecasting, and drought monitoring. However, it is still in the initial stage for some other applications (e.g., precision agriculture, forestry research), which is partly due to the limitations of current satellite products in terms of spatial and temporal resolution, and their limited ability to represent root zone soil moisture. In general, it is challenging to meet all the requirements of the broad user communities. One typical example is the accuracy requirement: large-scale climate-related applications and NWP only need accurate soil moisture temporal dynamics, while hydrological modeling and ecosystem monitoring require accurate absolute soil moisture values. Moreover, the requirements for soil moisture depth, temporal resolution, and quality information also vary with different applications (Table 2). A recent review by Peng et al. (2021) comprehensively summarizes gaps between current soil moisture products and various applications. To improve the characteristics of satellite soil moisture products further, close collaboration between data producers and various user groups is required. In addition, there is a strong demand for high spatial and temporal resolution soil moisture products in many disciplines. In the future, many applications will benefit from the availability of high-resolution soil moisture products, and more applications will emerge.

Conclusion and outlook

Remote sensing is an invaluable tool for obtaining frequent quasi-global soil moisture estimates. The number of satellites carrying instruments suitable for soil moisture retrieval has increased rapidly over the past decades, including two dedicated soil moisture missions that were launched in 2009 (SMOS) and 2015 (SMAP), respectively. Most of these satellites provide soil moisture estimates at a spatial resolution of 25²–50² km² with a global coverage every 2–3 days. Higher-resolution (1²–10² km²) products are available from synthetic-aperture radar instruments or obtained using downscaling algorithms or data assimilation techniques. Merging different satellite products can yield daily or even sub-daily soil moisture estimates almost everywhere on the globe. With

Table 2 Requirements of various applications on satellite soil moisture.

Application	Usage	Accuracy	Soil moisture depth	Temporal resolution	Other
NWP	Assimilation of soil moisture or low- frequency microwave brightness temperature into NWP system	Accurate temporal dynamics	Surface and root zone	Daily or subdaily	Reliable near real-time products
Climate	Evaluation of model performance and investigation of land-atmosphere interactions	Accurate temporal dynamics	Surface and root zone	Monthly or sub-monthly	Long-term soil moisture climatology
Hydrology	Hydrological modeling and estimation of water cycle components	Accurate absolute soil moisture	Surface and root zone	Sub-daily (e.g., hourly)	Reliable quality information
Agriculture	Precision agriculture and erosion modeling	Accurate absolute soil moisture	Root zone	Weekly and sub-weekly	Reliable quality information
Ecosystem	Ecosystem monitoring and ecological modeling	Accurate absolute soil moisture	Root zone	Weekly	Reliable quality information

the prospect of novel instrument technology of planned satellite missions and ongoing developments for retrieval, data merging, and downscaling algorithms, we can expect to approach sub-daily soil moisture estimates at an agricultural field scale with ever-improving accuracy in the years to come. This will help us to face and overcome some of the most pressing challenges of our time including climate change adaptation, food security, water resources management, and many others.

Abstract

Soil organic carbon (SOC) is one of the key indicators for soil quality and plays an important role in the global C cycle. Remote sensing techniques are rapidly evolving for mapping and monitoring SOC. Platforms range from unmanned aerial systems (UAS) to airborne and satellite systems. Multivariate analysis and machine learning techniques are used to calibrate SOC prediction models from the reflectance of bare soil surfaces in the visible, near infrared and shortwave infrared wavelengths (400–2500 nm). The principles of imaging spectroscopy, its application from UAS, airborne and satellite platforms and the challenges for the future of this rapidly evolving technique are discussed.

Glossary

Cellulose absorption index CAI $(0.5(R_{2.0} + R_{2.2}) - R_{2.1})$ describes the average depth of the cellulose absorption feature at 2100 nm, where $R_{2.0}$ is the reflectance at 2000 nm, $R_{2.1}$ at 2100 nm and $R_{2.2}$ at 2200 nm.

Chemometrics Refers to extracting information from chemical compounds using data-driven methods such as multivariate analysis, random forest and machine learning techniques.

Chromophore Is the part of the molecule responsible for its color.

Imaging spectroscopy Optical remote sensing observations and in particular reflectance spectroscopy at the remote sensing scale applied for the quantitative determination and modeling of a range of soil properties.

Normalized burn ratio2 (NBR2) Is a spectral index for multispectral satellites (such as Sentinel 2 and Landsat 8) and is calculated from the ratio of the reflectance in the SWIR bands $(SWIR1 - SWIR2)/(SWIR1 + SWIR2)$. The SWIR 1 (band 11) is at 1610 nm and SWIR 2 (band 12) at 2190 nm. For the Sentinel 2 multispectral instrument (MSI).

Normalized soil moisture index (NSMI) Is the ratio between the reflectance in the SWIR $(SWIR1 - SWIR2)/(SWIR1 + SWIR2)$, where SWIR 1 is at 1800 nm and SWIR 2 at 2119 nm. This index is currently only suitable for hyperspectral instruments.

Soil reflectance composite Mosaic of reflectance spectra from bare soil pixels collected over different years. Bare soil pixels are selected from the collection of satellite imagery based on thresholds of spectral indices enabling predominantly undisturbed soils to be separated from all other land cover types such as permanent vegetation and built up areas.

Soil spectral library Data set containing soil properties analyzed in the laboratory together with their reflectance spectra of dry, ground samples acquired with a laboratory spectrometer.

Key points

- SOC maps at the regional to continental scale are scarce and often very costly to update using conventional sampling and analysis techniques.
- Satellite data are freely available and have a relatively high spectral resolution and a revisit time of up to five 5 days. At higher resolution, multispectral cameras or mini spectrometers mounted on unmanned aerial systems (UAS) are also used.
- These technological developments have sparked the interest for SOC mapping and monitoring by remote sensing.
- Many studies still cover relatively small areas ($<200 \text{ km}^2$) within which fields have been selected that meet the optimal requirements for SOC prediction (dry, smooth topsoils without vegetation or residue cover). The number of calibration

samples is often limited and the use of large spectral libraries or soil data bases is often hindered by a lack of standardization.

- For larger areas or when considering multi-temporal reflectance composites, the topsoil conditions cannot be checked in the field. Therefore, thresholds of spectral indices are developed to select the optimal conditions.
- Both the developments in data processing and in sensor technology are rapid including geospatial processing platforms, lightweight spectrometers extending into the shortwave infrared (SWIR) for UAS systems and hyperspectral satellites with short revisit times.

Introduction

Soil organic carbon (SOC) plays a critical role in soil quality and the global C cycle. Soil organic matter and its main component SOC are dynamic properties that show large spatial variation even between fields and are frequently related to (historic) land use or land management. Unfortunately, SOC maps at the regional to continental scale are scarce and often very costly to update using conventional sampling and analysis techniques. Soil spectroscopy has become an established analytical technique for soil components such as C, N (nitrogen), clay and CEC (cation exchange capacity). Recently, similar spectroscopic techniques have been applied to optical remote sensing (RS) platforms offering the possibility of mapping large areas (Chabrilat et al., 2019). Reflectance spectroscopy at the RS scale, referred to as imaging spectroscopy (IS), or hyperspectral imaging, have been shown to be powerful techniques for the quantitative determination and modelling of a range of soil properties. Tziolas et al. (2021) reviewed the recent literature and found that the majority of RS studies dealing with soil properties focused on SOC (including soil organic matter). They showed that overall the quality of the SOC prediction models decreases from the field (median $R^2 = 0.63$) to the regional ($R^2 = 0.60$) and country/continental scale ($R^2 = 0.50$). When these models are applied to pixels with exposed soils, an up-to-date map of soil properties can be obtained that covers large areas and at the same time has a spatial resolution of 20 m (Sentinel 2) to 30 m (Landsat 8) and is detailed enough to show differences within and between fields. The satellite data are freely available and have a relatively high spectral resolution and a revisit time of 5 days (for the Sentinel 2 multispectral instrument (MSI)). For more detailed applications, such as precision agriculture multispectral cameras or mini spectrometers mounted on unmanned aerial systems (UAS) are already used (see the literature review by Angelopoulou et al., 2019). These developments have sparked the interest for SOC mapping and monitoring by remote sensing of either several fields by UAS borne sensors or for large areas by satellite imagery. Angelopoulou et al. (2019) mentioned six key advantages of remote sensing for soil property prediction: (i) a non-destructive technique, (ii) coverage of large areas, (iii) including inaccessible areas, (iv) possibility to predict several soil properties simultaneously, (v) provision of concise data and (vi) reduces the need for laborious sampling campaigns. With the increasing availability of low-cost sensors and high-quality satellite data there is an urgent need to improve automated procedures for the calibration of spectra and clearly define the conditions under which prediction models can be developed and applied for SOC mapping. Spectral models, however, only predict the SOC content for exposed topsoils and calibration models are sensitive to fractional cover by vegetation or residues, variations in moisture content and shading due to roughness. For reliable SOC maps, pixels influenced by such factors should be masked or the model should be corrected for them (Castaldi, 2021).

Here, we first discuss the principles of imaging spectroscopy, then demonstrate its application from airborne, UAS and satellite platforms and conclude with developments in the near future. Airborne applications have the longest history and so far, the highest spectral resolution. Recently, multispectral cameras and light weight spectrometers have been developed for UAS-borne applications. Although these techniques are still in full development, UAS are very flexible for SOC mapping at the field scale and have provided a level of SOC prediction comparable to one that can be obtained from traditional soil sampling and analysis (Andries et al., 2021). Satellite systems provide the benefit of a short revisit time and spatial resolution that can distinguish patterns within a field. There are already several studies that demonstrate the capability of these satellites, such as Sentinel 2 and Landsat 8, for detailed mapping and monitoring of topsoil properties (Tziolas et al., 2021). Some hyperspectral satellites such as the Italian PRISMA instrument are already operational or have recently been launched such as the German EnMAP instrument. It is expected that hyperspectral instruments on board satellite constellations will reach the same global coverage with short revisit time as the Sentinel 2 MSI in the next decades.

The principles of imaging spectroscopy

Soil spectroscopy registers the electromagnetic radiation emitted by a source and reflected by a soil surface. The wave lengths that are most often used either range from the visible light (Vis: 300–700 nm) through the near infrared (NIR: 700–1100 nm) to the short-wave infrared (SWIR: 1100–2500 nm), or cover the mid infrared region (MIR 2500–25,000 nm). Chemical and physical properties of soil compounds are related to the overall shape of the spectrum and to specific absorption bands (Stenberg et al., 2010). The SOC is a chromophore responsible for the soil color with absorption features in the visible wavelength range, (Fig. 1). Moreover, its absorption features in the SWIR range are overtones of vibrations in the MIR range due to stretching and bending of covalent bonds. In short, the correlation between spectra and soil properties is based on a chemometrics approach in which data

Fig. 1 A synthetic soil spectrum showing main soil chromophores.

mining techniques yield empirical relations between the reflectance at certain wavelengths and soil properties (Chabrilat et al., 2019). The multivariate analysis between the dependent variable (SOC content) and the independent variables (reflectance at different wavelengths) should take correlation between the independent variables into account. The most commonly used techniques range from multivariate regression such as partial least square regressions (PLSR) to decision trees such as random forest (RF) to machine learning techniques ranging from gradient boosting to support vector machines (SVM) and deep learning techniques such as convoluted neural networks (CNN; see for the recent literature (Tziolas et al., 2021)). These data mining techniques are trained on so-called spectral libraries containing both the spectra and the corresponding chemical or physical properties of a range of soil samples. Recently, large-scale spectral libraries covering entire countries (e.g., Australia, United States, Brazil) or continents (e.g., Europe or Africa) are becoming available.

Imaging spectroscopy has the advantage of producing a large amount of spatial soil data but at the expense of lower accuracy due to atmospheric absorption and lower spectral resolution, together with a reduced signal-to-noise ratio of the sensors (Angelopoulou et al., 2019). Compared to laboratory spectrometers, remote sensors have more difficulty in acquiring a signal from the soil surface under optimal conditions i.e., dry and smooth soils without crust, residues or vegetation. Moreover, the reflectance captured by a remote sensor originates from the surface and cannot be used to predict properties deeper in the soil profile. For temperate regions exposed soils occur mainly in cropland (Rogge et al., 2018). Cropland soils are frequently ploughed and the upper 10–30 cm are mixed creating a homogeneous SOC content. However, RS instruments capture a vegetation or residue signal for croplands throughout the largest part of the year. Vaudour et al. (2019a) investigated the performance of SOC prediction models for an agricultural area around Versailles (France) based on the spectra acquired by the Sentinel 2 MSI throughout the year. They found that most images were not suitable because of vegetation, residue cover, variation in soil moisture or roughness. A favorable time window for SOC prediction exists just after tillage and seeding (in spring and autumn for temperate regions) when the soils are exposed.

For calibration and validation geo-referenced soil property databases should be constructed or existing ones such as the European land use and coverage area frame survey (LUCAS; Tóth et al., 2013) can be used. The spectral signal acquired by the RS instrument is then matched with the soil property data from the corresponding pixel. Combining all calibration and validation data in this way will create an ad hoc spectral library with the soil property i.e., SOC content as independent variable and the reflectance (or absorbance) at the different wavelength as the dependent variables. Data mining techniques are then used to define the spectral soil property prediction model. The approach is comparable to the one used in laboratory spectroscopy with the exception that the spectra are acquired directly by the RS instrument instead of the laboratory spectrometer. To ensure validity of the calibration for the pixels of the RS instrument, it is recommended that composite samples are collected from the topsoil (0–15 cm and not deeper than the plough layer) covering an area the size of at least one pixel for satellite imagery or 3 by 3 pixels for imagery with 1–5-m resolution to take positional uncertainty into account. The three main factors affecting soil reflectance and accuracy of the model prediction have been assigned to: (1) the atmosphere; (2) a low signal-to-noise ratio of the imaging sensor data and (3) disruptive factors affecting the soil surface (partial vegetation cover, moisture, crust).

Dedicated sampling campaigns and analysis of soil properties for these ad hoc spectral libraries become the main constraints when, on the one hand, large areas that are targeted such as Sentinel 2 tiles or, on the other hand, UAS platforms are used to map several fields without a priori knowledge on the soil properties. In such cases, existing spectral libraries would offer a cost-effective alternative for calibration and validation. Unfortunately, attempts to transfer spectral models developed on laboratory spectral libraries (e.g., LUCAS) to predict a soil property using the signal of a satellite RS instrument have so far been unsuccessful. Soil standards scanned with both a master and a workhorse (slave) instrument in the laboratory have been used to predict soil properties scanned with the slave instrument using the spectral model developed with the master instrument (Kopačková and Ben-Dor, 2016). However, the transfer of models developed from a spectral library to the signal of a satellite or airborne RS instrument is not yet possible. The drawbacks are the lack of point specific correction models for atmospheric disturbance, the lack of soil standards for which a signal can be acquired by a RS instrument and the difference in spectral resolution between a laboratory spectrometer

(continuous with 1-nm band width) and a RS instrument (c. nine spectral bands mainly in visible and near infrared). For UAV borne instruments, Zhang et al. (2021) have shown that a spectral alignment procedure was needed when they predicted SOC content from the UAS spectrometer using a spectral model developed on a laboratory spectral library. Wehrhan and Sommer (2021) suggested a hybrid approach where topographic indices were used together with a reduced number of samples for the prediction of SOC content in an undulating morainic landscape. Both examples demonstrate the flexibility and effectiveness of UAS-borne instruments for mapping albeit for areas with a limited extent.

The most frequently used figures of merit for evaluating the accuracy of the SOC prediction models are the R^2 of the predicted versus observed SOC contents, the root mean square error (RMSE), the ratio of performance to deviation (RPD, i.e., the standard deviation divided by the RMSE) and the ratio of performance to interquartile range (RPIQ). Uncertainty of the SOC prediction in each grid cell is usually expressed as the ratio between the distribution of the model outcomes covering 90% of all possible cases (P95–P5) and the median model outcome. Examples of uncertainty maps are rare and the existing ones are often based on bootstrapping of the calibration dataset (Gomez et al., 2015).

Airborne platforms

The first airborne sensors were often push broom systems that collect data cubes at high spatial (2–5 m depending on the flight altitude) and spectral (200–300 spectral bands in the VNIR–SWIR) resolutions. The airborne campaigns can typically cover flight lines of 10–70 km long and up to 10 km wide (e.g., Stevens et al., 2010; Guo et al., 2019). The campaigns are generally organized when a large number of the fields have just been prepared for seeding. It is assumed that surface conditions are homogeneous and that the reflectance can be related to one or more soil properties. Overall, airborne campaigns give the best SOC prediction models among the RS platforms (Table 1). Shi et al. (2020) used a PLSR model to predict SOC content in croplands along a 66 by 7 km flight line in central Belgium using the spectra from the Swiss-Belgian Airborne Prism Experiment (APEX) sensor. They predicted SOC contents for the pixels with an NDVI (normalized difference vegetation index) ranging from 0.10 to 0.22, obtaining good results for an independent validation data set ($R^2 = 0.56$, $RMSE = 3.0 \text{ g C kg}^{-1}$, $n = 43$). Similar results were obtained by Guo et al. (2019) for a freshly ploughed field of $1.5 \times 1 \text{ km}$ in Iowa (USA) using an airborne Headwall sensor (400–1700 nm; SpecTIR LLC; $R^2 = 0.66$; $n = 55$). The spectral features related to SOC are often difficult to distinguish, in particular in the SWIR region where the signal-to-noise ratio is low. Therefore, some authors proposed ensembles of modelling approaches (Laamrani et al., 2019) in order to select the most important wavelengths for SOC prediction. Diek et al. (2016) were, to the best of our knowledge, the first to combine the spectra of flight campaigns carried out during consecutive years and thus created a multi-temporal composite. The advantage of such composites is that the area of bare soils increases, because with crop rotation different fields are exposed during the time windows when either summer or winter crops are sown. Until now, airborne sensors have provided the best spectral and spatial resolution compared to UAS and satellite platforms (Angelopoulou et al., 2019). However, flight campaigns are costly and difficult to organize as they are restricted to a limited time window when both atmospheric conditions are optimal and (a large portion of) the fields are in seedbed condition. Therefore, they are only available for limited areas and times, therefore multi-temporal composites like that of Diek et al. (2016) are extremely rare.

Unmanned aerial systems (UAS) platforms

The UAS are evolving rapidly and offer the potential for very high spatial resolution of SOC prediction in croplands. Such a resolution matches the needs for precision agriculture. At the same time, UAS systems are less sensitive to some disadvantages of space- and air-borne systems in particular atmospheric and surface conditions (Wehrhan and Sommer, 2021). Although UAS systems are constrained by payload, flight duration and legal restrictions, the organization of flight campaigns for one or several fields is quite flexible giving spatial coverage of up to a few hundreds of hectares (for a fixed wing UAS) and a spatial resolution of less than 1 m. Moreover, the flight campaigns can be easily planned to meet both optimal weather and soil conditions, minimizing atmospheric disturbance and disturbances at the soil surface such as roughness, moisture and residues. Recent literature reviews on the role of Earth Observation for SOC prediction mentions only a handful of papers using UAS borne sensors (Angelopoulou et al., 2019; Tziolas et al., 2021) (Fig. 2).

Light weight spectrometers and multispectral cameras are essential because the payload of UAS platforms is limited. Crucil et al. (2019) tested the performance of two mini spectrometers (STS-VIS and STS-NIR, Ocean Optics Inc., Dunedin, FL, United States) and two multispectral cameras (Sequoia, Parrot Drones, S.A, Paris, France) and Mini-MCA6 (Tetracam Inc., Chatsworth, CA, United States; Table 2) for their performance to predict SOC content in dried and ground soil samples. The prediction was compared to the one obtained with the ASD Fieldspec 3FR reference spectrometer (Analytical Spectral Devices Inc. Boulder, CO, United States). The tests were carried out in both the laboratory and outside under natural light. Moreover, transferability of the models between laboratory and natural light conditions was tested. The authors showed that the performance of lightweight sensors for SOC prediction was comparable to that of one of the reference instrument (ASD). Under outdoor conditions the best results were obtained using the vis-NIR range only, probably due to lower signal-to-noise ratio in the SWIR range as a result of atmospheric disturbance. Moreover, the multispectral camera gave similar or better results than the STS mini spectrometers.

Aldana-Jague et al. (2016) used a UAS-borne Tetracam Mini-MCA6 camera for mapping SOC content of the Hoosfield long term-trial at Rothamsted (United Kingdom). The soils are homogeneous with a rather strong gradient in SOC content ($8.2\text{--}46.7\text{ g C kg}^{-1}$). They corrected the camera for both systematic noise (using a dark surface in the laboratory) and for shadows along the outer edges of the images (using a white Lambertian surface). The SOC prediction model was robust with a cross-validation R^2 of 0.95 and an RMSE of 2.1 g C kg^{-1} . A good fit to the SOC patterns was obtained using an external validation

dataset (RMSE = 2.6 g C kg⁻¹). They also estimated the cost of their approach, consisting of 5 h for image acquisition and the collection of 30 calibration samples, 5 h of post processing and the cost of sample analysis, totaling 800 euros for a cropland field of between 2 ha and 10 ha. More recent SOC predictions at the field scale from UAS-borne platforms used the Parrot Sequoia and the MicaSense Altum dual sensor (MicaSense Inc., Seattle, WA, United States) with nine spectral bands in the vis-NIR range (Žižala et al., 2019; Biney et al., 2021; Table 2). Both studies were carried out in the Czech Republic on fields with a smaller range in SOC contents (c. 6–29 g C kg⁻¹). Žižala et al. (2019) obtained the best SOC prediction using the Cubist model and an external validation set ($R^2 = 0.72$; RMSE = 3.1 g C kg⁻¹). The predictions of the UAS-borne system correlated well with those from a hyperspectral airborne sensor and a Sentinel 2 composite. Unfortunately, the UAS-borne images from Biney et al. (2021) were affected by banding along the flight lines and the SOC prediction models were unsatisfactory ($R^2 = 0.22$).

Structure for motion algorithms is frequently used as a technique to match overlapping points in order to mosaic images of multispectral cameras. Their very high resolution allows residue, crop or shaded pixels to be included, which makes correlation with the calibration sample uncertain. Moreover, distortion along the edges of the images, vignetting, and anisotropic behavior resulting from variation in shading according to the flight direction are sources of errors often resulting in banding along the flight lines. Zhang (2022) demonstrated the necessity for data pretreatment of mosaics from a multispectral camera including correction for anisotropy, spatial resolution and resampling together with shadow and soil crust resampling. He predicted SOC content using a UAS-borne MicaSense Rededge-M camera with five spectral bands (475, 560, 668, 717 and 840 nm) for three fields in the Belgian loam belt with a mean SOC content of 10 g C kg⁻¹. The model performance (cross-validation) clearly improved from $R^2 = 0.33$ and RMSE = 2.9 g C kg⁻¹ without correction to $R^2 = 0.67$ and RMSE = 2.9 g C kg⁻¹ after correction for anisotropy, and crust and shadow removal.

The SOC prediction models discussed in the previous paragraph were specifically calibrated for each field. Given the flexibility of UAS platforms there is the potential to fly several fields and thus increase cost efficiency because calibration could be done using samples collected from a single field or even better using an existing (local) spectral library. Wehrhan and Sommer (2021) demonstrated a parsimonious approach using a Tetracam mini MCA 6 camera (Table 2). They used only eight calibration samples and included the topographic position index (TPI) indices together with spectral bands in their SOC prediction model. The cross-validation of their model using the reflectance at 570 nm and the TPI yielded an $R^2 = 0.91$ and an RMSE = 1.1 g C kg⁻¹ for one of the fields in the morainic landscape of northern Germany with a mean SOC content of 17 g C kg⁻¹. Moreover, they showed that the SOC model developed for one field also predicted the SOC content of an adjacent field reasonably well. Zhang et al. (2021) used a UAS platform with a portable Ocean FX spectrometer with a range from 350 to 1000 nm (Ocean Optics Inc., United States) together with a high precision RTK/PKK GPS to acquire precise geo-referenced spectra for a field in the Belgian loam belt. A local calibration based on correlating the spectra with SOC content from 179 samples at the collocated points yielded a good SOC prediction performance (RMSE = 0.57 g C kg⁻¹ and RPIQ = 2.35). However, as discussed above, the large number of samples required makes this approach inefficient. Therefore, they used a local spectral library to create an SOC prediction model and applied a spectral alignment procedure to resolve the discrepancy between UAS and laboratory measurements. Although the quality of the model decreased somewhat compared to the local approach (RMSE = 0.93 g C kg⁻¹ and RPIQ = 1.45), this provides a potential for mapping the SOC contents of multiple fields efficiently within the region.

Overall, the developments in UAS borne sensors and their SOC prediction models are promising. The SOC predictions have a high spatial resolution and are generally accurate. Flight campaigns are flexible and optimal weather conditions coinciding with minimal disturbance of the soil surface can be selected. Protocols are urgently required to deal with situations of inadequate

prediction models. They need to deal with mosaicking, corrections for the vignette effect, shade, crust, and anisotropy related to the orientation of the flight line with regard to the solar position. Moreover, an efficient calibration would reduce the costs and when stable would be applicable over an entire region.

Remote sensing of SOC from Orbit; towards continuous SOC maps over large areas

Recently, the archives of medium resolution satellite sensors (10–30 m) became freely accessible. There are several multispectral instruments (Landsat8 -operational land imager (OLI) from 1984 onwards and Sentinel 2 multispectral instrument (MSI) from 2015 onwards) and two hyperspectral instruments (Hyperion, 2000–2017 and PRISMA 2020 onwards). The Landsat 8 OLI has nine bands at 30-m resolution to cover the visible (coastal, blue, green and red), near infrared (NIR), shortwave infrared (SWR1 and SWR2) and thermal infrared regions (Fig. 3). The Sentinel 2 MSI has 10 bands at 10–20 m resolution to cover the visible (coastal, blue, green and red, near infrared (Red edge 1, Red edge 2 and Red edge 3)) and short-wave infrared (SWIR 1 and SWIR 2), while another three bands are for atmospheric correction at 60-m resolution. The favorable signal-to-noise ratio and the frequent revisit time (5 days for the Sentinel 2 and 16 days for the Landsat 8) of these multispectral satellites entails a large amount of freely available data and offers potential for soil property mapping. The use of hyperspectral satellites for soil property mapping is currently limited either by their spatial coverage or their medium signal-to-noise ratio. The Hyperion sensor on the EO (Earth observation)-1 satellite platform was the only hyperspectral sensor covering the vis-NIR-SWIR range in orbit (2000–2017). The sensor provided a spatial resolution of 30-m, a spectral resolution of 10 nm, a swath of 7.5 km and a low to medium signal-to-noise ratio (around 50; Gomez et al., 2008). The hyperspectral PRISMA sensor was launched in 2019. It has 66 bands in the vis-NIR and 171 bands in the SWIR with a bandwidth of c. 12 nm with a signal-to-noise ratio of 400–500 in the NIR and part of the SWIR and smaller values at both shorter and longer wavelengths. The spatial resolution is around 40 m and the swath 30 km resulting in a revisit time of 29 days.

So far, there have been only a limited number of studies using the hyperspectral satellites for SOC prediction. They covered relatively small areas with sparse vegetation or bare soils. Gomez et al. (2008) used a PLSR approach based on Hyperion data to predict SOC in cotton (*Gossypium hirsutum* L.) fields of New South Wales, Australia, and compared the results to spectra collected in the field using an Agri Spec spectrometer (Analytical Spectral Devices, Boulder, Colorado). Overall, the SOC prediction models from the Hyperion data gave reasonable results with $R^2 = 0.51$ and RPD = 1.43, but prediction with the field spectrometer was better

Fig. 3 Example spectra for crop residue, soil and green vegetation with and without simulated sensor noise and atmospheric correction residuals. Vertical tan bars represent the bands of the current Landsat Operational Land Imager (OLI) and the grey bars represent five shortwave infrared bands under consideration for a new version of the Landsat system. Reproduced with permission from Hively WD, Lamb BT, Daughtry CST, Serbin G, Dennison P, Kokaly RF, Wu Z and Masek JG (2021) Evaluation of SWIR crop residue bands for the landsat next mission. *Remote Sensing* 13(18). <https://doi.org/10.3390/rs13183718>.

($R^2 = 0.67$, RPD = 1.75). According to the authors, impurity of the Hyperion pixels (30 m) and the low signal-to-noise ratio explain this difference in performance. The Hyperion image of Lu et al. (2013) covered cropland in an area with a continental dry climate in China during the dormant season, when the soils were bare after wheat (*Triticum aestivum* L.) or potato (*Solanum tuberosum* L.) crops. They found that prediction performance for laboratory and simulated Hyperion spectrometry was better than that based on the spectra acquired by the satellite. The results of validation of the SOC prediction model based on Hyperion spectra ($R^2 = 0.50$; RPD = 1.45) were similar to the ones obtained by Gomez et al. (2008). Castaldi et al. (2016) evaluated the potential of future hyperspectral satellites. They used a spectral library for croplands in southern Italy ($n = 166$) and simulated the spectra based on the specifications of the PRISMA satellite and the forthcoming ones such as EnMAP and NASA-SBG (Surface Biology and Geology), the former HypsIRI mission. After considering atmospheric disturbance and the specified signal-to-noise ratio of the sensors they concluded that these forthcoming satellite missions could only marginally improve SOC predictions compared to existing hyperspectral or multispectral missions. The main constraint for the forthcoming satellites is still the low signal-to-noise ratio in the SWIR.

With the launch of Sentinel 2 MSI a large amount of spectral data at a revisit time of 5 days became available. This availability of frequent imagery offered the potential for SOC prediction in croplands where the time window during which the soil is bare is limited to a few weeks after harvesting and before seedling emergence (Diek et al., 2016). Several authors investigated the performance of SOC predictions based on Sentinel 2 images for various small regions with bare cropland soils and found that the SOC prediction models based on laboratory or airborne spectrometry were slightly better than those based on Sentinel 2 imagery (R^2 : 0.56; RPD: 1.0–2.6) (Gholizadeh et al., 2018; Castaldi et al., 2019; Vaudour et al., 2019b). Even with a slightly poorer SOC prediction performance, the SOC maps created using Sentinel 2 data display similar patterns to the maps based on airborne hyperspectral data and show coherent patterns (e.g., related to clay content).

Encouraged by the frequent revisit time of the Sentinel 2 MSI, Vaudour et al. (2019a) explored the performance of SOC prediction models established for croplands using a single Satellite 2 image at different acquisition dates. They targeted bare cropland soils with an NDVI < 0.35 and observed that performance of the PLSR models varied over time and that in general the best results were obtained for late spring when soils were probably drier and smoother after sowing (R^2 : 0.46–0.58; RPD: 1.4–1.5). The extent of bare soil varied together with development of the different crops, but for a single Sentinel 2 image it never exceeded 50% of the cropland area. Therefore, scientists are increasingly turning to multi-temporal methods of analysis, where soil reflectance composites are created by mosaicking the mean (or median) bare soil spectrum for each pixel acquired over a time span of several years. The first example of such an approach is the Geospatial Soil Sensing System (GEOS3) that creates a bare soil image after thresholding for green vegetation using NDVI and the residues with the SWIR bands (NBR2; Dematté et al., 2018). The soil composite mapping processor (ScMAP) uses annual development of the crop from exposed soil (after ploughing) to photosynthetically active vegetation cover occurring at least once per year (Rogge et al., 2018). For multi-temporal composites, they define minimum and maximum NDVI thresholds to separate cropland from other land uses.

Zepp et al. (2021) applied the SCMap soil reflectance composite approach to the Landsat archive images between 1984 and 2014 covering Bavaria. The random forest model showed the best performance when predicting SOC contents for croplands ($R^2 = 0.67$, RMSE = 1.24%, RPD = 1.77). Although the soil reflectance composites appear to provide a stable mean spectrum for predicting SOC contents, it remains challenging at the regional to country scale, and in particular for multi-temporal composites to minimize the effects of, for example green and dry vegetation, roughness, and soil moisture (Castaldi, 2021). Therefore, SOC prediction models should be formulated and applied using spectra of 'pure soil' pixels, i.e., dry soils without green or dry vegetation and reduced roughness (e.g., soil in seedbed condition; Castaldi, 2021). The spectra of green vegetation and residues are clearly different from a soil spectrum and the same applies to a dry and a wet soil spectrum (Fig. 3). Spectral indices have been developed to mask green vegetation (the well-known NDVI), crop residues (cellulose absorption index; see e.g., Hively et al., 2021) and soil moisture (normalized soil moisture index, NSMI; see e.g., Chabrilat et al., 2019). Unfortunately, the narrow SWIR bands that are required for CAI and NSMI cannot be picked up by the Sentinel 2 or Landsat multispectral instruments (Fig. 3). Nevertheless, PLSR models applied to soil reflectance composites of the spring months have shown reasonable model performance during 10-fold cross-validation for a Sentinel 2 tile T31UFU covering the area to the North and North East of Amsterdam (The Netherlands; $R^2 = 0.49$; RPD = 1.4; RMSE = 3.49 g C kg⁻¹; Fig. 4). An independent validation ($n = 28$) showed that for 74% of samples the measured SOC value was within the prediction interval of the spectral model. Regional trends in SOC contents can be observed in the reclaimed IJsselmeerpolders where croplands dominate. The Wieringermeer polder in the North is the oldest (drained in 1927) and overall has larger SOC contents than the Noordoost polder (drained in 1942) and the Flevopolder (eastern part drained in 1957 and southern part drained in 1968). The Noordoost polder includes some former peat islands and although these are mainly under grassland, the lake sediments around their edges are thin and remnants of peat have been mixed into the plough layer. This is evident in the larger SOC contents near Urk, Schokland and Lemmer (Fig. 4).

The examples of surface reflectance composites in the previous paragraph demonstrate that deviating spectra related to disturbance of surface conditions disappear in the mean spectrum. Alternatively, algorithms can be formulated to select optimal spectra only that represent 'pure' soil pixels. Time series of Sentinel 2 imagery during the growing season can help to distinguish the optimal period for SOC prediction i.e., the last image before the crop starts to develop (Dvorakova et al., 2021). This approach improves the PLSR models for SOC prediction using all cloud free Sentinel 2 images over a 2-year period in the Belgian loam belt: selecting all images: $R^2 < 0.30$, RPD < 1.4 to selecting only the greening up phase and an NBR2 < 0.07: $R^2 = 0.54$, RPD = 1.68. This strict selection targets soils under seedbed conditions. These are overall smooth, bare and the surface dries quickly. However, a limit of this method might be the restricted coverage of the total cropland area, which reached only 62% compared to 95% when only an NDVI threshold was applied.

Fig. 4 Soil organic carbon map based on reflectance composites of the spring months from 2016 to 2021 of Sentinel 2 tile T31UFR covering the northwestern part of the Netherlands. Open Street Map has been used as a base map.

Outlook (limitations and future developments)

There are rapid developments in SOC mapping and monitoring using EO technology from both UAS platforms and orbit. The number of studies for UAS systems is still limited, but are increasing. The freely available Sentinel 2 and Landsat 8 archives have triggered the interest of many researchers. Several projects have started to improve SOC prediction for croplands and are moving towards operational systems for mapping and monitoring SOC contents in topsoils at continental and even global scales (e.g., World Soils financed by the European Space Agency and STEROPES financed by the European Joint Program Soil). Below we discuss the main limitations that still exist for operational SOC mapping and monitoring followed by suggestions for remediation:

- Limitation of the area covered and data to be shared:** Many studies still cover relatively small areas ($<200 \text{ km}^2$) within which fields have been selected that meet the optimal requirements for SOC prediction (dry, smooth topsoils without vegetation or residue cover). The number of calibration samples is often limited and the use of large spectral libraries or soil data bases is often hindered by a lack of standardization. Recently, there are several initiatives to foster standardization of the measurement protocols for both wet chemistry and laboratory spectral measurements (including instrument standardization). The P4005—Standards and protocols for soil spectroscopy—within the Institute of Electrical and Electronics Engineers (IEEE) standards organization was launched recently to formulate agreed protocols for spectral measurements. Such a standardization would allow data exchange between spectral libraries and thus offer the possibility of large calibration data sets and the use of more advanced machine learning techniques for EO based SOC prediction. The global soil laboratory (GLOSOLAN) initiative of the FAO has already started on the standardization of laboratory protocols for wet chemistry and has recently created a working group for soil spectroscopy. The Open Soil Spectral Library launched by Soil Spectroscopy 4 Global Good is a first step towards a freely accessible spectral library that builds on the exchange between existing continental scale libraries.
- Limitations of thresholds for bare soil detection:** For larger areas or when considering multi-temporal reflectance composites, the topsoil conditions during flight cannot be checked in the field. Therefore, thresholds of spectral indices are developed to select the optimal conditions. Unfortunately, such indices do not exist to distinguish rough soils. The indices for moisture and residues are in the SWIR. At present the multispectral satellites have only two broad bands in the SWIR that react simultaneously, but not very specifically, to moisture and residue (Fig. 3). Hively et al. (2021) suggested adding three narrow bands in the SWIR for the next generation of Landsat sensors. The cellulose absorption index (CAI) based on the reflectance of narrow bands at 2040,

2100, and 2210 nm has a strong potential to detect residues. For detecting roughness in freshly ploughed fields synthetic aperture (SAR) radar data acquired by Sentinel 1 can offer a solution (Vaudour et al., 2019a).

- **Limitations of infrastructure capabilities:** The wealth of EO data is likely to increase with the advent of hyperspectral satellite systems. The European Commission together with the European Space Agency (ESA) have developed Copernicus Data and Information Access Services (DIAS), geospatial processing platforms with a soil mapping orientation. This service provides continuous access to Copernicus, as well as cloud storage and computing resources. These services will need to be extended to cover the provision and processing of future hyperspectral satellite data. Sensors are rapidly evolving towards micro-electromechanical systems (MEMS) for UAS platforms and hyperspectral sensors for satellites. Although SWIR cameras for UAS still need to be optimized in terms of size and weight, and the auxiliary devices needed during flight have to be miniaturized, first models are just becoming available (e.g., HySpex Mjolnir S-620 from Norsk Elektro Optikk, NEO). Regarding hyperspectral satellites, the Italian PRISMA sensor has been operational since 2020 and is the first of a series of high signal-to-noise ratio instruments with a high spatial resolution and a limited coverage per day satellite imaging spectrometers. Planned missions with similar instruments are: the German EnMAP (Environmental Mapping and Analysis Program), the Japanese HISUI (Hyperspectral Imager Suite), and the Italy-Israeli SHALOM (Spaceborne Hyperspectral Applicative Land and Ocean Mission). Moreover, several global mapping missions are planned such as the NASA-SBG (Surface Biology and Geology), HySpex2 proposed as Earth Explorer Mission ESA and the Sentinel-10/CHIME satellite proposed as the ESA candidate mission (Copernicus Hyperspectral Imaging Mission for the Environment). These satellites will be a major step forward as they will improve SOC prediction capabilities of EO systems compared to the currently available multispectral satellites such as Sentinel 2 and Landsat 8.

Abstract

Pedotransfer functions (PTFs) are equations that use basic soil attributes, such as soil texture and soil bulk density, which are easier to measure, to predict those that are harder to determine, such as soil hydraulic parameters, for modeling relevant earth system processes. Here, we give a general overview of PTF development with a focus on soil hydraulic attributes and discuss different categories of PTFs. Frequently used metrics for PTF optimization and evaluation are summarized. We conclude the Chapter by providing an example application of how PTFs are used in modeling soil water movement and how uncertainty in soil hydraulic parameter estimates propagates to derived state variable quantities.

Glossary

Hydraulic parameter Hydraulic parameter is a parameter that quantitatively describes a soil hydraulic property. Several hydraulic parameters are used in soil hydraulic functions.

Pedotransfer function Pedotransfer function is an equation that uses basic soil attributes, such as soil texture and soil bulk density, that are relatively easy to measure, to predict those that are harder to determine, such as soil hydraulic parameters.

Soil hydraulic characteristic Soil hydraulic characteristic is the relation between soil matric potential and soil water content (also known as the water retention characteristic) and the relation among soil matric potential, water content and soil hydraulic conductivity (hydraulic conductivity characteristic), and is also called the soil hydraulic function.

Soil hydraulic conductivity Soil hydraulic conductivity is a property of porous material, describing how easy a fluid (usually water) can pass through the pore space. It depends on the intrinsic permeability of the material, the degree of saturation, and on the density and viscosity of the fluid.

Soil hydraulic property Soil hydraulic property is a property that controls the water retention, infiltration, rate of water flow, and the fate of chemicals and pollutants in soil. This property is largely affected by various intrinsic soil characteristics, such as soil texture, bulk density, porosity, structure, and the interactions of these properties with each other.

Soil water retention Soil water retention is the relationship between the water content and the soil matric potential, which is characteristic for different types of soil, and is also called the soil moisture characteristic, water retention characteristic or pF characteristic.

Vadose Zone Vadose Zone is the variably saturated zone between the ground surface and the permanent water table of the groundwater.

Key points

- An overview of pedotransfer functions (PTFs) focusing on soil hydraulic attributes is presented.
- Different categories of PTFs and evaluation criteria to evaluate the developed PTFs are discussed.
- An example application of how PTFs are used in modeling soil water movement is provided.

Introduction

Soil science, hydrology, and earth science in general require accurate descriptions of the systems under study (Vereecken et al., 2022). The relevant domains typically range from individual soils, entire critical zone systems for ecosystem services, to detailed continental to globally distributed data to assess and predict changes in water, carbon, and global climate cycles. Our capability to monitor, visualize, and detect ecosystem changes by remote sensing has seen an astounding development over the past decades. It is now sometimes possible to “see” details with publicly available remote sensing platforms at a level of detail that was previously the domain of well-funded national security agencies. Likewise, developments in computer science allow us to establish detailed global datasets of what cannot be easily seen from space. In the past decades, detailed soil databases and geographic information systems (GIS) have been established to provide a highly detailed global distribution of soil texture, organic carbon, and bulk density, among many other soil attributes relevant to ecosystem features and services (Hengl et al., 2017).

The collection, archiving, documentation and publishing of historic as well as up-to-date earth systems data are necessary but often insufficient by themselves to make assessments of past, present, and future changes in local, regional, and global environmental systems. In many cases, we can only make those assessments by using deterministic or stochastic models to obtain the requisite data relevant to scientists, policymakers, and other stakeholders. These models require data that is either unavailable or only available at an insufficient level of detail. At the same time, the models themselves may not yield immediately useful output for the scientist, stakeholder, or policymaker. In many cases, available earth systems data and earth-systems model output must be transformed or translated to be useful.

The infiltration of water in soils is a critical aspect of the terrestrial hydrological cycle and is relevant, for example, for crops and ecosystems, trafficability of land, and flooding (Vereecken et al., 2019). Infiltration is, among other factors, governed by hydraulic conductivity and can be modeled using a range from simple statistical to complex 3D dynamic simulations. While hydraulic conductivity *can* be measured in the laboratory and field, it is expensive to do so, often requiring hundreds to thousands of dollars per soil profile. Suppose there was a need to simulate infiltration for all terrestrial ecosystems at a scale of 250 m; roughly half a billion measurements of hydraulic conductivity would be needed, which would require an insurmountable investment in financial and labor resources. Intuitively, however, hydraulic conductivity can be related to soil particle-size distribution, soil bulk density, and perhaps other factors. As a simple example: it is fairly obvious that a loose (coarse-grained) sandy soil should have a greater hydraulic conductivity and, therefore, a faster infiltration rate than a dense clay soil. Global soil texture data are available at a 250 m resolution (Hengl et al., 2017). If suitable deterministic or statistical models or even simple tabulations can be established that capture the relation between hydraulic conductivity and texture, soil bulk density, and geomorphological or geological factors, we would be able to estimate hydraulic conductivity for the requisite half billion grid-cells.

In essence, pedotransfer functions address the “major challenge for soil science . . . to “translate” data we have to data we need.” (Bouma, 1989). Although the above example has a hydrological focus, it is equally well possible to extend the concept to other relevant earth system factors, such as thermal properties of soils or ecosystems (as relevant for terrestrial energy balances), soil chemical transport (nutrient and other chemical balances), as well as biological parameters (Van Looy et al., 2017).

This chapter will first focus on the general context of pedotransfer functions for estimating soil hydraulic properties and briefly review their history. Next, we will briefly discuss the different pedotransfer functions (PTFs) categories. Finally, we will provide an example of how PTFs might be used in assessing a long-term water balance of a deep vadose zone.

General overview

The term “Pedotransfer function” was first published by Bouma and van Lanen (1987) with the following definition (Bouma, 1989):

Pedotransfer functions “... relate different characteristics to one another or to land qualities. Two types of pedotransfer functions are distinguished. Those with continuous characteristics are called: continuous pedotransfer functions. Those using class characteristics are called: class pedotransfer functions.”

Land Qualities in this context are:

“... attribute of land which acts in a distinct manner in its influence on the suitability of land for a specific kind of use. Land qualities may be expressed in a positive or negative way. Examples are moisture availability, erosion resistance, flooding hazard, nutritive value of pastures, accessibility.”

Fig. 1 PTFs are usually a small part of a larger project enabling the generation of data that is important for scientists, engineers, policymakers, or other stakeholders. They do their work by estimating difficult to measure hydraulic properties, $\theta(h)$ and $K(h)$, from more widely available basic soil properties such as soil texture (TXT), bulk density (BD), organic matter (OM) or other soil characteristics. Various types of PTF exist, and here we sketched two: one is a class PTF, the other one is a continuous PTF. Depending on the application, practitioners may prefer one over the other.

The transfer function concept outlined by Bouma and van Lanen is general and is used in a wide range of earth science applications (Van Looy et al., 2017). In soil science and hydrology, PTFs are usually employed to convert basic soil data such as soil texture, soil bulk density, and other informative data into more difficult to measure soil hydraulic properties, such as soil water retention $\theta(h)$ and hydraulic conductivity $K(h)$, where h is matric potential.

Fig. 1 (simplified after Bouma, 1989) depicts two types of PTFs, i.e., class and continuous PTFs, which predict hydraulic properties for a soil water model. The model is driven by boundary conditions and simulates time series of matric potential h , water content θ , and water flux v as a function of time t and position z , denoted as $h(t, z)$, water content $\theta(t, z)$, and water flux $v(t, z)$. Matric potential and soil water potentials in general are the physical drivers of water fluxes in soils, resulting in accumulation or depletion of soil water content. These state variables must be further aggregated to provide meaningful outputs for stakeholders.

The hydraulic properties are one component in the system depicted in Fig. 1, but are often difficult to obtain in the laboratory. However, usually available are soil survey or land classification maps, digital terrain models, and detailed interpolated maps for soil attributes, such as texture, bulk density, and organic carbon or organic matter content (Tóth et al., 2014). Hydraulic PTFs enable us to transform the soils and landscape data into the hydraulic properties needed for a simulation model (or any other application that needs hydraulic properties). There is a fairly large variety of ways by which existing PTFs can be classified: e.g., by what kind of hydraulic properties are estimated, by required input data (or predictors), by mathematical structure, and whether single or multiple models are used to make estimates.

PTF categories

PTF output

Before discussing the different methods by which PTFs can be established, we must first consider their desired output. As mentioned previously, hydraulic properties are difficult to obtain directly in the field or in the laboratory, but databases representative of a wide range of soil types of such properties and related data have been collected by various groups around the world. Such databases typically contain hydraulic properties as pairs of water content and matric potential (θ, h), hydraulic conductivity and matric potential (K, h), or hydraulic conductivity and water content (K, θ), each of which has been determined for multiple values of θ and

Table 1 Hydraulic functions: the Brooks-Corey, van Genuchten, and Kosugi retention functions and their corresponding hydraulic conductivity formulation through application in the [Mualem \(1976\)](#) pore-connectivity theory.

	Retention function $\theta(h)$	Hydraulic conductivity function $K(h)$
Brooks and Corey	$\theta = \begin{cases} \theta_r + (\theta_s - \theta_r) \left(\frac{h_0}{h} \right)^\lambda & h < h_0 \\ \theta_s & h \geq h_0 \end{cases}$	$K = \begin{cases} K_s S_e^{2/n+L+2} & h < h_0 \\ K_s & h \geq h_0 \end{cases}$ with $S_e = (\theta(h) - \theta_r)/(\theta_s - \theta_r)$
Parameters	4: $\theta_r, \theta_s, h_0, \lambda$	1: K_s with $L = 0.5$ 2: K_s, L
van Genuchten	$\theta = \begin{cases} \theta_r + \frac{(\theta_s - \theta_r)}{[1 + \alpha h ^n]^m} & h < 0 \\ \theta_s & h \geq 0 \end{cases}$	$K = \begin{cases} K_s S_e^L \left[1 - (1 - S_e^{1/m})^m \right]^2 & h < 0 \\ K_s & h \geq 0 \end{cases}$ with $S_e = (\theta(h) - \theta_r)/(\theta_s - \theta_r)$
Parameters	4: $\theta_r, \theta_s, \alpha, n, m = 1-1/n$	1: K_s with $L = 0.5$ 2: K_s, L
Kosugi	$\theta(h) = \theta_r + \frac{1}{2} (\theta_s - \theta_r) \operatorname{erfc} \left[\frac{\ln(h/h_m)}{\sqrt{2}\sigma} \right]$	$K = K_s S_e^L \left\{ \frac{1}{2} \operatorname{erfc} \left[\frac{\ln(h/h_m)}{\sqrt{2}\sigma} \right] + \frac{\sigma}{\sqrt{2}} \right\}^2$ with $S_e = (\theta(h) - \theta_r)/(\theta_s - \theta_r)$
Parameters	4: $\theta_r, \theta_s, h_m, \sigma$	1: K_s with $L = 0.5$ 2: K_s, L

Models are given with their canonical parameters.

h for a particular soil, or soil sample. In many cases the measured sets of paired values are not uniform because they were obtained with different objectives or derived from different laboratories using different measurement techniques.

To harmonize hydraulic property datasets into uniform characteristics, it is often necessary to describe the relationship between soil water content, θ , and matric potential, h , with a soil water retention function. Many formulations exist, and in [Table 1](#) we provide three of the most common functions used in PTF development: the [Brooks and Corey \(1964\)](#) model (BC), the [van Genuchten \(1980\)](#) model (VG), and the [Kosugi \(1996\)](#) model. Each of these soil water retention functions has four parameters, two of which describe the maximum (saturated) water content, θ_s , and the residual water content, θ_r , which is a minimum possible value. The other two parameters ($\{h_0, \lambda\}$, $\{\alpha, n\}$, and $\{h_m, \sigma\}$ for BC, VG, and Kosugi, respectively), are known as shape parameters, which determine the position and sharpness of the decrease of water content from saturation to residual water content as a function of matric potential. Through the application of [Mualem's \(1976\)](#) pore-size theory, a corresponding hydraulic conductivity function can be derived with at least one parameter: saturated hydraulic conductivity K_s , i.e., the hydraulic conductivity at saturation where $\theta = \theta_s$ and $h = 0$. Parameter, L , determines the rate of decrease in hydraulic conductivity and is often set to 0.5 after [Mualem \(1976\)](#). As a result, water retention and hydraulic conductivity can be described with five parameters for each of the three hydraulic functions. PTFs that predict these parameters can therefore provide a complete, though not necessarily an accurate or precise description of both hydraulic functions. We refer the reader to [Brooks and Corey \(1964\)](#), [van Genuchten \(1980\)](#), and [Kosugi \(1996\)](#) for details regarding assumptions, mathematical derivation, and the interpretation of parameters.

If standardized hydraulic measurements are available at specific matric potentials, the PTF developer has the option to build a model that predicts moisture content at these specific points. Such point-PTFs have some benefits as the fitting of hydraulic functions—which imparts some error to the estimates—can be bypassed. Point PTFs are useful if the user is interested only in field capacity or wilting point, both of which are available in many databases for PTF development ([Tóth et al., 2014](#)). When the developer decides to estimate the hydraulic parameters of one of the models in [Table 1](#), the PTF is called a parametric PTF.

Predictors

Predictors are variables that, by theoretical or statistical analysis, should be related to desired quantities. In the case of PTFs for water movement, predictors are input variables that feed into mathematical formulae, which then provide information about the values of the five hydraulic parameters identified previously. There is no rule on which predictors *should* be used, and developers often use a

heuristic approach to identify which predictors are available to them and which combination of these works best in terms of objective statistical criteria. Successful predictors usually exhibit correlations with hydraulic data in initial data exploration and most PTFs at least include soil texture class or soil particle size data as the most basic input, since these properties represent the most fundamental physical characteristics of soils.

Additional input data commonly used in PTFs includes soil bulk density and organic carbon content or organic matter content. These properties will mainly affect porosity, soil water retention, and K_s . It should be noted that bulk density and organic carbon content are often intercorrelated and that using both as predictors may not substantially improve the accuracy of PTFs. Bulk density and porosity are very dynamic properties and are affected by land use change, tillage practice, trafficking, weathering, or drainage. Soil organic carbon content is much less dynamic and affects soil adsorption properties by its large surface area and its role as gluing agents, (e.g., microbial gums and polymeric substances), and therefore, it will also affect the soil water retention and other soil hydraulic properties. Minasny and McBratney (2018) investigated the effects of soil organic matter content on the available water capacity based on a meta-analysis from more than 50,000 measurements around the globe, and concluded that organic matter content in soil has a small effect on available water capacity.

Infrequently used PTF predictors include soil chemical, soil morphological properties and soil structural information. Soil chemical properties include pH, cation exchange capacity (CEC), sodium adsorption ratio (SAR), and calcium carbonate (CaCO_3) content and may be necessary to improve PTFs (Tóth et al., 2014). Soil morphological properties, such as pedogenic horizon type, consistence, mottles, and concretions, are typically described in the soil survey but are often qualitative or semi-quantitative, which is more challenging to integrate into PTFs. Soil structure is the spatial arrangement and ordering of soil particles, determining the pore size distribution, tortuosity, and connectivity. Soil structure can be utilized to represent the biological activities (soil fauna and vegetation), abiotic factors (freezing-thawing and wetting-drying processes), or the effects of tillage practices in the soil. The role of soil structure on hydraulic processes is complex, and soil structure itself is difficult to quantify; therefore its role is typically unaccounted for when developing PTFs, which is increasingly seen as a knowledge-gap (Van Looy et al., 2017).

Some PTFs have used soil water retention data as predictors in addition to basic soil properties, such as soil texture and bulk density (for example, see Rawls et al., 1992; Schaap and Leij, 1998). This choice may seem odd because the objective of many PTFs is to estimate water retention. The input of one or two water retention points can be justified by the fact that most other predictors only show a modest correlation with the desired hydraulic properties, which can be mitigated substantially by using a single retention point as a predictor. It is found that this strategy often substantially improves PTF performance, with the drawback that water retention at specific matric potentials must be available to use the particular PTF.

PTFs with hierarchical predictors

Developers of PTFs often use a combination of intuition and statistical algorithms to select predictors that yield the “best” PTF, given a database with predictors and hydraulic parameters. In general, such approaches tend to favor PTFs that use several predictors as input (e.g., sand, silt, clay, bulk density, and organic matter content). The drawback of such an approach is that all these predictors *must* be available when the PTF is used, which potentially limits the applicability of the PTF because not all predictors may always be available.

Rather than striving for the goal of the best PTF, it is sometimes advantageous to develop PTFs with more limited sets of predictors, especially if it is known which predictors likely users of the PTFs have access to. The literature provides several of these approaches, such as Rawls et al. (1992) and Vereecken et al. (1989, 1990). More recently, Tóth et al. (2014) proposed a structured approach to develop hierarchical point and parametric PTFs for use in spatial applications in which not all data may always be available. As an example, Table 2 shows Rosetta 3 (abbreviated as R3), a hierarchical PTF model developed by Zhang and Schaap (2017) with five PTFs that uses progressively more predictors to estimate soil hydraulic parameters, including K_s and soil water

Table 2 Performance of the hierarchical Rosetta 3 PTFs in estimating van Genuchten soil hydraulic parameters (see Table 1 for the parameters), as published by Zhang and Schaap (2017).

		RMSE Calibration	RMSE Independent data	RMSE Calibration
Rosetta 3 ^a (R3)	Predictors	Soil water content (θ) ($\text{cm}^3 \text{cm}^{-3}$)	Soil water content (θ) ($\text{cm}^3 \text{cm}^{-3}$)	Log transformed saturated soil hydraulic conductivity $\log(K_s)$ (–)
R3H1	USDA Class	0.074	0.0681	0.739
R3H2	Sand, Silt, Clay	0.072	0.0628	0.726
R3H3	Sand, Silt, Clay, and Bulk density	0.062	0.0589	0.672
R3H4	Sand, Silt, Clay, Bulk density, and θ_{33}	0.040	0.0342*	0.600
R3H5	Sand, Silt, Clay, Bulk density, θ_{33} , and θ_{1500}	0.039	0.0260*	0.600

Model evaluations were performed on an independent global dataset by Zhang et al. (2020), except those marked with * which were unpublished. The global data set was selected from NCSS and included 116,641 data points from 49,855 samples, but slightly fewer for R3H4 and R3H5 as requisite data was unavailable. Zhang et al. (2020) were not able to evaluate soil hydraulic conductivity (K_s) for the Rosetta 3 PTFs. θ_{33} and θ_{1500} are water contents at -33 kPa (field capacity) and -1500 kPa (plant wilting point), respectively. RMSE is root mean square error.

^aRosetta 3 is a hierarchical set of five PTF models that use progressively more predictors to estimate soil hydraulic parameters, including saturated hydraulic conductivity (K_s) and soil water retention parameters (θ_r , θ_s , α , n).

Table 3 The Rosetta3 R3H1 Class PTF for the van Genuchten (1980) hydraulic functions.

	θ_r	θ_s	$\log_{10}(\alpha)$	$\log_{10}(n)$	$\log_{10}(K_s)$
Clay	0.131	0.457	-2.067	0.0986	1.169
Silty clay	0.124	0.473	-2.000	0.105	0.983
Sandy clay	0.147	0.382	-1.601	0.0922	1.055
Clay loam	0.107	0.429	-2.002	0.143	0.849
Silty clay loam	0.120	0.470	-2.255	0.157	1.046
Sandy clay loam	0.0934	0.380	-1.906	0.116	1.122
Loam	0.0902	0.402	-2.197	0.153	1.125
Silty loam	0.0832	0.427	-2.465	0.191	1.266
Sandy loam	0.0606	0.380	-1.785	0.163	1.573
Silt	0.0650	0.472	-2.219	0.198	1.641
Loamy sand	0.0582	0.383	-1.609	0.230	2.034
Sand	0.0546	0.363	-1.484	0.462	2.808

The parameters α , n , and K_s are given as $\log_{10}$ values because these have approximately log-normal distributions. The unit for θ_r , θ_s , α , n , and K_s are $\text{cm}^3 \text{cm}^{-3}$, $\text{cm}^3 \text{cm}^{-3}$, cm^{-1} , dimensionless, and cm day^{-1} , respectively.

retention parameters (θ_r , θ_s , α , n). The first version of Rosetta can be found under the link (<https://www.ars.usda.gov/pacific-west-area/riverside-ca/agricultural-water-efficiency-and-salinity-research-unit/docs/model/rosetta-model/>). The first model (R3H1) is simply a class PTF for each USDA texture class (see Table 3 for the Rosetta 3 class PTF to estimate the parameters of the van Genuchten hydraulic functions). The second model (R3H2) utilized the sand, silt, and clay fraction of the soil as input, with estimated soil hydraulic parameters continuously varying with soil particle fractions. From the third to the fifth model (R3H3 to R3H5), bulk density, water content at -33 kPa (θ_{33}), and water content at -1500 kPa (θ_{1500}), respectively, were included as input. The motivation for using water contents as predictors in R3H4 and R3H5 was to maximize PTF performance for the comprehensive NCSS soil database, thus extending the availability of limited water retention data to a full set of hydraulic functions. Water retention at these two matric potentials were available in nearly 400,000 records for over 60,000 soils predominantly from the USA and its territories, as well as several thousands of soils from non-USA regions.

Table 2 illustrates that increasing the number of predictors generally improves PTF accuracy, here defined in terms of root mean square errors (RMSE) for soil water content (θ) and K_s . The class and texture-only models (R3H1 and R3H2, respectively) both have similar errors, but estimates improve substantially when bulk density is added with R3H3. Adding retention data at -33 kPa yields a further improvement, indicating that not all relevant information is carried in soil texture and bulk density. Supplementing a second retention point at 1500 kPa yields little additional improvement. The above indicates that R3H4 or R3H5 should be used if their predictors are available (which they often are in the NCSS data), but that users can fall back to R3H3, R3H2, or R3H1 if constrained by the availability of input data. Because models R3H1 to R3H5 have been developed on the same database it is more likely that estimates among different models are consistent, something that cannot be guaranteed if PTFs developed on different databases are used (see Schaap and Leij, 1998). Table 2 shows a rare case when the RMSEs for independent data are smaller than for the data used to develop the model, presumably because the independent NCSS data used uniform methodologies for measuring hydraulic properties and predictors, whereas there was a large diversity in measurement methodologies used to obtain the R3 data.

PTF development strategies

PTFs can be developed using several standard statistical techniques that we categorized below into some general classes. Fig. 2 shows a generalized approach that involves a database with both predictors and hydraulic parameters, a candidate PTF with an internal structure (e.g., linear equation or machine learning), and internal empirical coefficients. These coefficients are adjusted through an iterative model development process followed by the minimization of the objective function, which calculates the sum of the squared differences between the measured and predicted properties or parameters (see Section "Calibration metrics"). The value of the objective function allows an algorithm to adjust the internal model coefficients. We also refer the reader to Tóth et al. (2014) who presented a comprehensive structured analysis of what kind of PTF to develop depending on conditions of data availability and target application.

Semi-physical approaches

Nearly all PTFs are empirical, focusing on statistical relations between predictors and hydraulic parameters without relying on theoretical concepts. Semi-physical approaches exist, however, such as Arya and Paris (1981) who proposed a direct relationship that scales the soil particle size distribution into a soil pore size distribution. The pore size distribution is then converted into capillary pressure by relating to the Young-Laplace equation, whereas volumetric soil water content is obtained by distributing the total pore volumes from the bulk volume. The calculated capillary pressure and volumetric water content are then paired to obtain the soil water retention curve. Arya et al. (1999) refined the Arya and Paris (1981) model by considering different scaling parameters that converted the soil particle size distribution into the soil water retention curve. One of the disadvantages of this method is that

Fig. 2 Generalized PTF development schematic. There is nothing inherently magical about PTFs and their development uses well-established statistical techniques. A developer establishes a database with paired sets of predictors and hydraulic parameters. The developer also chooses a statistical framework (class PTF, regression, or machine learning) for the PTF and possibly decides upon the internal model structure (which can also be selected automatically in some frameworks). Initially, the model starts off with arbitrary model coefficients, but an iterative application of model predictions and objective function evaluations allows these coefficients to be optimized.

detailed soil particle size distribution data must be available, which makes it difficult to be applied in most practical cases. Recent developments in particle size analysis, however, may allow this approach to be revisited.

An alternative physical approach to establishing the relationship between input and output variables is to use computational fluid dynamics simulations. For example, [Zhang and Schaap \(2019\)](#) carried out a Lattice Boltzmann simulation based on a synthetic porous medium. They found that using particle size to estimate saturated hydraulic conductivity is not entirely correct and that hydraulic radius (pore volume over solid phase surface area) is more appropriate. However, this approach is computationally expensive and requires Computed Tomography (CT) and subsequent image analysis to derive the pore structure of soil samples. Similar approaches for water retention have been attempted (see [Schaap et al., 2007](#)), but the two-phase nature of this approach is even more demanding. Presently, estimates of hydraulic properties assisted by fluid dynamics simulations are still at the proof-of-concept stage without immediate usefulness for PTF users.

Class and continuous PTFs

[Bouma \(1989\)](#) identified two main types of PTFs: class and continuous PTFs (see also [Fig. 1](#)). Class PTFs are the simple yet widely used PTFs, which provide class-average soil hydraulic parameters as a look up table for each of the 12 USDA textural classes. Because of their simplicity, class PTFs have been widely used in soil hydrology and Earth system science. For example, the work by [Cosby et al. \(1984\)](#) and [Clapp and Hornberger \(1978\)](#) are employed by land surface models. Other class PTFs include the R3H1 model ([Table 3](#)), which is used in the Hydrus 1D soil water model ([Simunek et al., 2005](#)). Class PTFs are often the least demanding for data input as they can be used in conjunction with subjective data such as “hand texture” soil survey data. A distinct drawback of class PTFs is that they permit no variation of hydraulic properties within each class, but instead exhibit discrete changes at class boundaries. Class PTFs depend on pre-defined textural or other soil classes, but there is no guarantee that these class boundaries are appropriate for PTFs, as shown in a study that used k-means clustering to classify continuous PTF output ([Twarakavi et al., 2010](#)).

Continuous PTFs utilize continuous soil properties, such as sand, silt, clay fractions, bulk density, and soil organic carbon content, as input, therefore relieving the discontinuity issue of class PTFs. Continuous PTFs, however, require regression or machine learning approaches (see next two sections) to relate predictors of hydraulic parameters and are therefore more complex than class PTFs.

Regression approaches

Many of the well-established PTFs were developed based on regression approaches. [Gupta and Larson \(1979\)](#) were probably the pioneers in building a linear regression approach to estimate the soil water retention characteristics. The main advantage of the regression approach is that they can be easily implemented in spreadsheets or program code. However, the drawback of the approach is that the mathematical model structure must be chosen before calibration and that it may be difficult to capture complex non-linear relations among predictors and hydraulic parameters. The latter problem can partially be mitigated by using variable transformations prior to PTF development, or by the use of more complex or nested regression equations, as applied by, e.g., [Pachepsky et al. \(1998\)](#) using the group method of data handling (GMDH). [Table 4](#) shows the simple [Cosby et al. \(1984\)](#) PTF for estimating Brooks-Corey parameters; most other regression PTFs are considerably more complex.

Table 4 The two-variable Cosby et al. (1984) PTF for estimation of Brooks and Corey (1964) parameters.

Variable	Equation	Units
θ_r	0	$\text{cm}^3 \text{ cm}^{-3}$
θ_s	$(50.5 - 0.142 \times \text{sand} \% - 0.037 \times \text{clay} \%) / 100$	$\text{cm}^3 \text{ cm}^{-3}$
$\text{Log}_{10}(h_0)$	$1.54 - 0.0095 \times \text{sand} \% + 0.0063 \times \text{silt} \%$	cm
λ	$1 / (3.10 + 0.157 \times \text{clay} \% - 0.003 \times \text{sand} \%)$	–
$\text{Log}_{10}(K_s)$	$-0.884 + 0.0153 \times \text{sand} \%$	inch/h

Machine learning approaches

Machine learning approaches, also known as artificial intelligence, have become a powerful tool and offer exciting new opportunities in extracting patterns and insights from predictor-output relationships. Neural networks (NNs), inspired by the biological nervous systems, are probably among the most widely used. NNs typically consist of multi-input and multi-output data transformation structures containing adjustable coefficients and offer two distinct advantages over traditional regression approaches. Firstly, whereas regression approaches can only estimate one hydraulic parameter for each equation (Table 4), NNs can predict all five in a single computation step. Secondly, no mathematical model must be chosen a priori with NNs. Instead, the predictor-output relations are “learned” automatically by the NN optimization algorithm and implemented in coefficient matrices. Drawbacks of NNs are their high computation requirements and that their outputs are not easily published in a human-readable form, for example, compared with the Class PTF in Table 2 or the Cosby et al. (1984) model in Table 4. A NN essentially consists of matrices with floating point numbers, which by themselves defy interpretation: it is nearly impossible to tell what the NN is “doing.” Because of this, special care needs to be taken when establishing NN models in general as a sufficiently complex NN will be able to reproduce the calibration dataset verbatim, but have inferior performance on new data. It is therefore advisable to split calibration databases into independent calibration, validation, and testing subsets (Guo et al., 2017). The calibration subset is often used to fit the models; the validation set is utilized to estimate prediction error for selection of the calibrated model; the testing set is used for assessment and quantifying of the generalization error of the final selected model.

Support vector machines (SVMs) are an alternative method for building predictive models such as PTFs. Twarakavi et al. (2009) built SVM-based PTFs and found that SVMs outperformed NN-based PTFs, such as Rosetta (Schaap et al., 2001). In addition, other machine learning approaches, such as decision or regression trees (Tóth et al., 2015) and the k-nearest neighbor method (Nemes et al., 2006), have been widely used to develop PTFs. New machine learning technologies, such as deep neural networks, and convolutional neural networks appear to be promising future research avenues for PTF development.

PTF replicas and PTF ensembles

All PTFs have inherent (but often ignored) uncertainties in their predictions. For example, the values listed for the R3H1 class PTF in Table 2 may give the impression that these are the “true” values for each parameter in each USDA textural class. This is incorrect, and each of these parameters has a very substantial standard deviation (not listed), which for $\log_{10}(K_s)$ amounts to 0.5 or more (see Zhang and Schaap, 2017). In practice, this means that there is an uncertainty in K_s of half an order of magnitude. The source of uncertainty is inherent in the source data used to establish class or continuous PTFs: both predictors, as well as hydraulic parameters vary substantially even for the same soil.

Uncertainty for class PTFs can be computed as simple standard deviations or standard errors (as necessary for the application). Uncertainty in estimates by continuous PTFs is more difficult to assess and may need sophisticated propagation of error approaches, depending on the mathematical structure of the model. A fairly simple way to quantify uncertainty in statistical models, PTFs included, is to repeatedly subset into calibration and validation subsets, using, e.g., the Bootstrap algorithm (Schaap and Leij, 1998) or simple repeated splitting of the data using random selection without replacement. By calibrating the PTF on each of the subsets (or “replicas”), small variations in PTF estimates will result, which can be quantified by mean and variance, as well as higher order moments, provided a sufficient number of replicas are used. The R3H2 to R3H5 hierarchical models in Table 2 were calibrated on one thousand replicas, allowing the determination of correlation among predicted hydraulic parameters, as well as their uncertainty.

Applications in soil hydrology, and most Earth system models often use only one single PTF to estimate the soil hydraulic parameters (Van Looy et al., 2017). Neuman (2003) suggested that describing the complex system and quantifying the associated processes with only a single model and one parameterization often underestimates the model uncertainty and, therefore, leads to over-confidence in predictive capabilities and decision-making. Tebaldi and Knutti (2007) suggested that estimates based on the outputs from an ensemble of many models (multi-model ensemble estimates) generally increase the reliability and reduce the inconsistency of the model estimation. The improvement of predictive skills by multi-model ensemble is based on the theory that each member of the ensemble models is independent and the errors are inclined to cancel or at least be partly reduced. In addition, the uncertainty of the ensemble model should be reduced as the number of ensemble members increases, resulting in an improvement of the predictive skill relative to the constitutive ensemble members. The most important and challenging work to derive ensemble models, therefore, is to assign suitable weighting factors for each ensemble member. Guber et al. (2006) and Zhang et al. (2020) are variations on this approach.

Calibration metrics

The mathematical frameworks to establish PTFs between predictors and output variables are exceedingly diverse. With the exception of class PTFs all PTFs contain parameters that must be optimized by minimizing the differences between measured and estimated properties as

$$\chi^2 = \sum_{i=1}^N (\zeta'_i - \zeta_i(\mathbf{b}))^2 \quad (1)$$

where ζ'_i and ζ_i indicate estimated and measured hydraulic quantities, N is the number of measurements, $\mathbf{b}$ is a vector, containing the empirical PTF coefficients. ζ'_i and ζ_i can be used to indicate either the estimated and measured or fitted parameters of the soil hydraulic functions in parametric PTFs, such as the parameters of equations in Table 1, or data points of estimated and measured water retention or hydraulic conductivities in point PTFs. It is noted that some of the hydraulic parameters (e.g., hydraulic conductivity or parameters describing pore size distribution, such as n in the van Genuchten model) has to be log-transformed before optimizing Eq. (1). The motivation behind the transformation is to convert the distribution into a Gaussian distribution.

Evaluation criteria

When a PTF model is built or selected in an application, statistical criteria are available to evaluate and quantify the *accuracy* and *reliability* of PTFs in estimating soil hydraulic parameters. *Accuracy* is often used to quantify the differences between estimated and measured quantities for model building, whereas *reliability* is utilized to assess the differences between estimates and measurements on validation data. A PTF may perform accurately based on the calibration data, but the assessment of independent data may not show reliable estimation, especially when the validation datasets are significantly different from the calibration data. In addition, some factors may not be included as predictors, such as climatic conditions and geographical locations of the soils, leading to systematic errors. Minasny and Hartemink (2011) found that PTFs developed in temperate climate regions are likely to produce remarkable errors for soils in tropical regions. While this is often the case, data sets from similar climatic conditions often present different input-input and input-output correlation structures, and it has been suggested that it is the similarities or differences in data correlation structure rather than purely the climatic origin that will drive a PTFs performance for a given validation data set (Fuentes-Guevara et al., 2022).

Root mean square error (*RMSE*), mean error (*ME*), and coefficient of determination (R^2) are the most commonly used indicators to measure the model performance. The *RMSE* is defined as

$$RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^N (\zeta'_i - \zeta_i)^2} \quad (2)$$

ME is used to quantify the systematic bias of estimations relative to the measurements, defined as

$$ME = \frac{1}{N} \sum_{i=1}^N (\zeta'_i - \zeta_i). \quad (3)$$

ME is negative when the PTF underestimates the quantity being evaluated, and positive if it overestimates it. When both *RMSE* and *ME* are small, the PTFs performs well. However, note that *ME* is the average value over the entire evaluated set of data points, and it is possible that overestimation and underestimation for different portions of the data domain are canceled out. Therefore, *ME* should be interpreted with caution. Calculating absolute mean errors can partially help address this problem. An additional way to help diagnose the uneven distribution of residuals is by correlating estimation residuals to the model inputs and outputs. A PTF performs optimally if any such correlations are small, but this is difficult to assess due to the smoothing nature of PTFs (i.e., their general bias toward the population mean).

R^2 is defined as

$$R^2 = 1 - \frac{\sum_{i=1}^N (\zeta_i - \zeta'_i)^2}{\sum_{i=1}^N (\zeta_i - \bar{\zeta})^2} \quad (4)$$

where $\bar{\zeta}$ is the average of ζ . R^2 normally ranges from 0 to 1, with higher values indicating a better fit.

Example application

In this section, we will provide an example of how PTFs might be used in a land surface or vadose zone study and illustrate how PTF uncertainty and variability propagates to derived quantities, such as vegetation transpiration, water storage, and groundwater recharge.

Background and assumptions

We selected three PTFs (R3H1, R3H2, and R3H3, see Table 2) from Zhang and Schaap (2017) and the PTF published by Wösten et al. (1999). More PTFs could have easily been evaluated but would have complicated this demonstration. PTF input data was derived from a previous study by Zhang et al. (2016), who studied infiltration in a deep vadose zone through a PTF-assisted model inversion. The purpose of the presented simulations is not to closely represent the conditions present at the site. Rather, we aim to illustrate the uncertainty and variability brought about by the PTFs themselves and hence, we simplified boundary conditions and some site characteristics.

The subject of the study is the Maricopa Infiltration site at the University of Arizona's Maricopa Agricultural Center (between Tucson and Phoenix in Southern Arizona). At this site, we have detailed textural and bulk density data for a 15-m deep alluvial profile (Schaap, 2013). Located in a semi-arid climate, this profile is unsaturated to a depth of 15 m where a perched groundwater table is found. A hypothetical type of vegetation was "grown" in the profile. The rooting depth of this vegetation was 100 cm, and the vegetation was assumed to be dormant between December 1st and May 1st. Vegetation coverage was assumed to be 50%, effectively meaning that the vegetation was exposed to 50% of potential evapotranspiration.

Long-term meteorological data are available through The Arizona Meteorological Network (AZMET), providing a 30-year record of daily measurements of precipitation and estimate of potential evaporation. Data for Tucson, about 100 km south, were selected as these provided the longest time series. For the purposes of this study, we increased precipitation by a factor of two, while keeping potential evaporation constant. This increase was necessary to simulate deep recharge to the groundwater. As such, the simulation did not reflect the reality present at the site's location.

The simulation was carried out with a command-line version of Hydrus-1D (Simunek et al., 2005) and input and output were generated or processed with a number of shell-scripts in a Linux environment. Hydraulic properties were generated with four PTFs for each 25 cm increment to 15 m depth (see Fig. 3). Two types of simulations were run: one for each of the four PTFs with the objective to demonstrate the variability among different PTFs. The objective of the second simulation was to illustrate the variability in simulated output brought about by uncertainty in a single PTF. To this end, we repeated the simulations for 100 of the 1000 replica estimates in the R3H3 model (see Zhang and Schaap, 2017), which contain substantial non-Gaussian bi-variate variability among the five estimated hydraulic parameters of the van Genuchten hydraulic functions (Table 1). For the purposes of this example, we set $L = 0.5$ (Mualem, 1976; see also Table 1).

Estimation and simulation results

The leftmost column of Fig. 3 shows the approximate color of the profile, as well as the texture and bulk density at each 25 cm depth increment. Immediately to the right of the profile, we graphed the estimated hydraulic parameters against depth for R3H1 (blue), R3H2 (green), R3H3 (red), and Wösten et al. (1999) (orange). For R3H3 we also plot the 10–90% probability (light gray) distribution and the 25–75% probability distribution (dark gray).

R3H1 (blue) is a class PTF with a tabulation of hydraulic parameters for each 12 USDA textural classes. For this reason, R3H1 estimates exhibit discrete jumps, as the texture at different depths belongs to different USDA classes. R3H2 (green) is a continuous function that only considers sand, silt, and clay percentages as input, which yields estimates close to those of the R3H1 class values. Bulk density is used in R3H3 and, since bulk density increases with depth, the estimated θ_s and K_s values decrease because the total porosity decreases. Because R3H1 and R3H2 do not use bulk density as the input, they overestimate the θ_s at deeper depths.

With the exception of θ_s and K_s (as discussed), the R3 hierarchical models tend to produce outputs similar to R3H1 and R3H2. This is because each of these models has been calibrated on essentially the same data, except that the number of input variables was more limited for R3H1 and R3H2. The Wösten PTF predicts rather different output (except for θ_s), simply owing to the fact that it was calibrated on data of a different source. The Wösten PTF produces lower θ_r (it is set constant at $0.01 \text{ cm}^3 \text{ cm}^{-3}$), n and K_s values, but higher values for α . We also show the parameter uncertainty for R3H3 as 10–90% (light gray) and 25–75% (dark gray) quantiles. The uncertainty is considerable and tends to increase with depth because most soil databases lack data from high-density samples, leading to uncertainty in the predictions for such soils.

Simulation results appear on the right-hand side of the figure, with the top panel displaying atmospheric boundary conditions (black: precipitation, blue: potential transpiration), root zone matric potential (second panel), total profile water storage in the third panel, and infiltration, transpiration, evaporation (offset), and drainage fluxes in the bottom panel. Colored lines, which sometimes overlap, indicate the PTFs mentioned previously. The light gray and dark gray areas are valid for the 10–90%, and 25–75% quantiles for the simulation using R3H3, with the black line representing the mean of simulated values for each of the 100 replicas.

Yearly evaporative demand is nearly 2200 mm, while this simulation only has an average of 540 mm annual precipitation. As a result, the internal dynamics of the profile are strongly controlled by root water uptake, which becomes leaf transpiration, and evaporation from the soil surface. Even with doubled precipitation, there is a strong rainfall deficit, resulting in a root zone that dries out quickly starting in May (when the vegetation becomes active) and—provided there is rainfall—wets up again in December, when the vegetation becomes dormant. As a result, the root zone matric potential is binary: it switches from a high value of around -300 cm in the winter period to -9000 cm during the growing season, at which matric potential the model was parameterized not to allow any root-water uptake. Owing to the strong atmospheric demand, there is very little substantial difference among PTFs with

Fig. 3 Implementation of PTF estimates within a vadose zone context. The leftmost column shows the approximate coloring of a 15-m-deep vadose zone profile at the Maricopa infiltration site. Colored lines in this column indicate sand, silt and clay percentages (blue, green, and red, respectively) as well as bulk density. Estimates of the VG parameters and K_s are shown in the adjacent five columns for the R3H1 (blue) class PTF, and the R3H2 (green), R3H3 (red), and Wösten (orange) continuous PTFs. For the R3H3 we also provide uncertainty in the PTF predictions as 10–90% and 25–75% quantiles (light and dark gray, respectively). The graphs on the right-hand side indicate the input and processed results of Hydrus-1D simulations for a 30-year time series. In the top diagram we show precipitation (black) and potential evapotranspiration (blue), which are boundary conditions to the simulation, as well as a constant groundwater level at 15-m depth. The second diagram holds the mean root-zone (0–1 m depth) matric potential. The third graph provides the mean water volume for the entire 15-m profile. The bottom graph holds the cumulative water balance fluxes: infiltration (purple), root water uptake (or plant transpiration), evaporation from the soil surface, and bottom drainage to the groundwater. The colors in these diagrams correspond to those of the PTF prediction. Single simulations were performed on VG + K_s parameters predicted by the R3H1, R3H2, and Wösten PTFs; for the R3H3 model we carried out simulations for the first 100 replicas that underlie the Rosetta PTFs.

regard to matric potential. This can be understood by realizing that matric potential is a controlling factor in root water uptake, surface evaporation, and—with gravitational potential—vertical transport of liquid water.

By contrast, very substantial differences exist among the PTFs in terms of total profile water storage (third right panel of Fig. 3, note that the vertical axis does not start at zero). It appears that R3H1 typically simulates “wetter” profiles than R3H2, which is wetter than R3H3. These systematic differences are because these three hierarchical PTFs are based on different predictors (see Table 2), and therefore predict different values of hydraulic parameters (see the left-hand side of Fig. 3), which results in different simulations. The Wösten PTF, which was established on a different calibration database, has different patterns still: it starts drier than Rosetta, until the year of 1993, when it becomes wetter than any of the R3 results. This is due to an extreme rainfall event for which each of the three R3 models produces more drainage than does the simulation based on the Wösten PTF.

The third panel also shows considerable variation among the 100 replica simulations for R3H3. This implies that even for a single PTF, there is substantial uncertainty not only in the hydraulic parameters it predicts, but also in the outcome of simulations that rely on these estimates (here about 20–40%). It is also important to point out that there are differences between the red and black lines. The red line reflects the single simulation based on the mean parameters of R3H3. By contrast, the black line reflects the mean of the simulations, which is slightly wetter. The difference between the two can be the result of two factors. Firstly, it is known that the R3 model estimates have non-Gaussian distributions with heavy tails (Zhang and Schaap, 2017). Secondly, vadose zone water transport has nonlinear characteristics, which can skew simulated outcomes.

The bottom diagram in Fig. 3 shows cumulative fluxes: infiltration (purple), root water uptake, evaporation (which is offset by 200 mm for visualization purposes) and bottom of profile drainage that essentially translates to groundwater recharge. Infiltration

(precipitation) is the same for all simulations as no runoff was simulated. There is some PTF-induced variability in root water uptake (simulations based on the Wösten PTF generate higher amounts) but surface evaporation is nearly the same for all simulations. Relatively large variability (and for R3H3 large uncertainty) exists for simulated bottom-of-profile drainage. Here the simulation based on the Wösten PTF simulates the smallest amount, whereas for R3H1 to R3H3, and the replica mean are quite similar. The variability about the replica mean is around 20–30% of the final value, implying that there is uncertainty in the simulated recharge.

The above results are for only one profile in a semi-arid deep vadose zone, and different soil, vegetation, and climate conditions may yield different results. We also make no claim here as to which PTF is actually superior, but merely emphasize PTF variability and uncertainty. Overall, the above analysis illustrates a number of important points.

- Irrespective of the used PTF, the simulations yield similar (almost identical) results in terms of matric potential. This may be convenient, since many soil-vegetation-hydrology processes are driven by matric potential, although it should also be mentioned that in the present case the extreme ET demand drives all simulations to a similar state during the growing season: a dry state with limited water supply to the vegetation.
- At the same time, applications that rely on the *amount* of water in soils should carefully consider the variability displayed in the third right panel: different PTFs yield different amounts. Although the simulated temporal dynamics induced by different PTFs are approximately the same, volume (mass) based applications require careful selection of PTFs. Studies that rely on the effective soil dielectric constant or rely on variations in gravitational acceleration (e.g., the GRACE satellites) may be especially sensitive to variability among PTFs.
- The choice of PTF may also affect simulations of large-scale groundwater recharge and energy partitioning at the surface. Simulations that generate higher transpiration amounts tend to have lower recharge amounts.

Summary

Direct measurement of certain soil attributes is often difficult, expensive, time-consuming, and impossible at larger spatial scales. As an alternative, the science community has developed *pedotransfer functions* (PTFs) to estimate these from more readily available soil properties (e.g., soil texture, bulk density, and organic carbon content). This allows the estimation of soil hydraulic parameters, as well as other relevant earth system properties, such as thermal properties, solute transport, and biogeochemical parameters. Reliable soil hydraulic parameters, for example, are critical for the representation of soil hydrological processes (e.g., partitioning of water at the land surface, movement and redistribution of water within the soil profile, soil evaporation and plant transpiration, and deep drainage at the bottom of the root zone) in soil science, hydrology, and earth system science.

In this chapter we focused on PTFs for soil hydraulic parameters. A general overview of PTF development was given, and different categories of PTFs were discussed, including different desired parameters of soil hydraulic functions, predictors, and development strategies. Semi-physical approaches, such as the work done by Arya and Paris (1981), and physical approaches carried out by computational fluid dynamics were briefly analyzed. Empirical approaches were briefly introduced, including class and continuous PTFs, regression approaches, and more advanced machine learning approaches. Uncertainty is inherent to PTFs and can be quantified by model replication strategies. We highlighted developing PTF ensemble models to increase reliability and reduce the inconsistency of the PTF estimation.

An example application of how PTFs might be used in soil hydrology and how the uncertainty of the estimated soil hydraulic parameters from PTF propagate to derived state variable quantities, such as matric potential, water volume, etc., was provided. The simulation examples show that although different PTFs can reach consistent results in terms of matric potential for a vegetated semi-arid site, variable and uncertain results are obtained for simulated water volumes and fluxes. The choice of PTF can therefore significantly impact derived quantities and conclusions while conveying significant uncertainty.

Abstract

Geostatistics, which was developed originally for mining, is now widely used for prediction of soil conditions at unvisited sites and for mapping from sample survey data. The technique is based on models of spatial variation. Soil properties are treated as the outcomes of random spatially correlated processes, to which may be added fixed effects of geographic trend or correlation with other environmental variables. Prediction proceeds from sample data in two stages, namely (1) estimation of spatial covariances or semivariances to which are fitted plausible variogram models, and (2) kriged predictions based on the variogram models. A figure shows how comparisons between data can be binned to estimate semivariances; others show popular variogram models. The techniques for stage 1 are illustrated with examples from soil survey; equations define the kriging systems to predict without bias and minimize the prediction error variances for stage 2. Residual maximum likelihood (REML) is now best practice for estimating simultaneously coefficients of fixed effects and parameters of the variograms of random residuals for universal kriging and kriging with external drift. Thousands of published accounts attest to the merits of geostatistics for spatial prediction and mapping of soil properties.

Key points

- Geostatistics is a technology for predicting values of variables at places from more or less sparse sample data.
- It is based on the theory of regionalized variables, that is, of spatially correlated random variables.
- Crucial to any prediction is a model of the covariance structure of the random process, usually expressed in the variogram.
- The prediction itself, kriging, is an unbiased and minimum-variance weighted moving average of data with the weights determined from the variogram.
- Ordinary kriging, the basic technique, can be elaborated to take into account fixed effects such as those of geographic trend and subsidiary covariates and of coregionalized random variables.
- Geostatistics is now widely applied for mapping plant nutrients and pollutants in soil and to salinity and its remediation, and it is being combined with remotely sensed data and machine learning for spatial prediction.

Introduction

Geostatistics has its origins in the gold mines of South Africa. The main problem from a statistical point of view was to estimate from small core samples the concentrations of gold in rocks and the amounts of metal in blocks of rock still in place ahead of the mining fronts. Only if those blocks contained sufficient gold to justify extraction would they be mined. Engineer D.G. Krige realized that such estimation was a form of spatial prediction and that by taking into account the spatial correlation among cores he could predict concentrations more precisely than by the conventional methods of estimation current then, the 1950s, and without the bias that typical mine sampling could incur (Krige, 1951). Krige's procedures were put on a sound theoretical footing by G. Matheron in the 1960s (Matheron, 1965), and for the next two decades applications in mining and petroleum engineering burgeoned, aided by the authoritative text by Journel and Huijbregts (1978). The method of prediction itself came to be known as 'kriging'. During that time soil scientists became similarly concerned; they were disappointed that the predictions from soil classification failed to take into account the similarities over short distances on the ground within those classes. They would need to express those similarities in terms of spatial correlation and apply the same techniques as the miners were using for prediction at unvisited places. They also found that in many instances classification conferred no benefits. Their main aim became to interpolate and map soil properties from measurements at more or less sparse sampling points. Burgess and Webster (1980) reported the first accounts of their success, since when applications in soil science have also burgeoned.

Random variables and random functions

Geostatistics is a technology. It is based on models of spatial variation, and to understand how it works one must first understand what is meant by 'model' in this context. Soil conditions are determined by agents of the environment acting on rocks and sediments, but such is the resulting complexity that they are indistinguishable from random. Fig. 1 is an example showing how the clay content of the soil varies along a transect across Jurassic scarplands of south central England. Table 1 summarizes the data. Geostatistically-minded soil scientists, pedometricians, therefore treat soil properties as random; they have in their minds a model in which the actual value $z(\mathbf{x})$ at any point $\mathbf{x}$ on the land surface is one drawn at random from a variable $Z(\mathbf{x})$, a population with potentially an infinity of values there. In principle a point may be in one, two or three dimensions, but in almost all applications each position is in two, so that $\mathbf{x} \equiv \{x_1, x_2\}$. Further, pedometricians assume that the values of z at all such points, again potentially infinite in number, in a region are drawn from a random process $Z(\mathbf{x})$ in those same dimensions. The model is then represented as

$$Z(\mathbf{x}) = u(\mathbf{x}) + \varepsilon(\mathbf{x}). \quad (1)$$

Fig. 1 Observed percentages of clay in the soil along a transect across Jurassic scarplands in central England; (A) topsoil and (B) subsoil.

Table 1 Summary of 321 observations of clay content (recorded as % by weight) in topsoil and subsoil as percentages.

	Topsoil	Subsoil
Mean	25.6	39.0
Median	20.0	36.0
Variance	255.49	936.81
Standard deviation	16.0	30.6
Skewness	1.2	0.2
Correlation coefficient	0.59	

Here $u(\mathbf{x})$ is the mean of the process at $\mathbf{x}$; it is a constant there but may vary from place to place. It is often termed 'trend' or 'drift'. The quantity $\varepsilon(\mathbf{x})$, in contrast, is a random variable with mean zero and variance σ^2 . Thus the model is a mixed one of fixed and random effects. The model is more often than not simplified to one in which $u(\mathbf{x})$ is treated as constant, the mean μ throughout the region of interest, and the model becomes

$$Z(\mathbf{x}) = \mu + \varepsilon(\mathbf{x}). \quad (2)$$

The random variable $Z(\mathbf{x})$ is then said to be stationary in the mean.

In design-based estimation, which dominated survey statistics from the 1920s and in which the sampling points are chosen independently at random, the $\varepsilon(\mathbf{x})$ are independent of one another. Their covariances are therefore zero:

$$\text{Cov} = [\varepsilon(\mathbf{x}_i), \varepsilon(\mathbf{x}_j)] = E[\varepsilon(\mathbf{x}_i), \varepsilon(\mathbf{x}_j)] = 0 \quad \text{for all } \mathbf{x}_i \neq \mathbf{x}_j, \quad (3)$$

where $\mathbf{x}_i$ and $\mathbf{x}_j$ are any two places on the ground.

Random sampling in mines is not feasible, nor would it be efficient. In soil survey it is more efficient and easier to sample on grids. Grid sampling provides even coverage and limits prediction error variances. In these circumstances the $\varepsilon(\mathbf{x})$ s can no longer be treated as independent of one another; they in turn must be modelled, and in practice they are modelled as functions of their separation on the ground:

$$\text{cov} [\varepsilon(\mathbf{x}_i), \varepsilon(\mathbf{x}_j)] = c(\mathbf{x}_i - \mathbf{x}_j) = C(\mathbf{h}). \quad (4)$$

With constant mean Eq. (3) is equivalent to

$$\begin{aligned} \text{cov} [Z(\mathbf{x}_i), Z(\mathbf{x}_j)] &= E[Z\{(\mathbf{x}_i) - \mu\} \{Z(\mathbf{x}_j) - \mu\}] \\ &= C(\mathbf{h}). \end{aligned} \quad (5)$$

In two dimensions the separation $\mathbf{h}$, called the 'lag,' is a vector comprising both distance and direction. The covariance decreases towards zero as the separating distance, $|\mathbf{h}|$, increases. At the other extreme, $|\mathbf{h}| = 0$, the covariance is $\sigma^2 = C(0)$, the variance of $\varepsilon(\mathbf{x})$. Division of $C(\mathbf{h})$ by $C(0)$ gives the dimensionless spatial correlation:

$$\rho(\mathbf{h}) = C(\mathbf{h})/C(0). \quad (6)$$

If $C(\mathbf{h})$ and therefore $\rho(\mathbf{h})$ are greater than zero then the random process, $Z(\mathbf{x})$, is said to be spatially correlated, or 'autocorrelated' because z is same soil property at all places $\mathbf{x}$.

In many instances practitioners cannot assume that the mean is constant. In those circumstances they cannot assume that the covariance exists. While they may be unwilling to assume that the means are constant throughout their regions of interest they might assume the mean to be constant for small to moderate $|\mathbf{h}|$, so that differences in $Z(\mathbf{x})$ between places separated by $\mathbf{h}$ would be zero:

$$E[Z(\mathbf{x}) - Z(\mathbf{x} + \mathbf{h})] = 0. \quad (7)$$

This observation provoked Matheron to replace the covariances for expressions of spatial correlation by variances of the differences in Eq. (7) thus:

$$\begin{aligned} \text{var} [Z(\mathbf{x}) - Z(\mathbf{x} + \mathbf{h})] &= E[\{Z(\mathbf{x}) - Z(\mathbf{x} + \mathbf{h})\}^2] \\ &= 2\gamma(\mathbf{h}). \end{aligned} \quad (8)$$

Eqs. (7), (8) constitute Matheron's intrinsic hypothesis, and random variables with these properties are said to be intrinsically stationary. In combination they release practitioners from the constraints of second-order stationarity and provide a wider field of application. The quantity $\gamma(\mathbf{h})$ is called the 'semivariance' at lag $\mathbf{h}$; it is half of the variance of the difference in $Z(\mathbf{x})$ between two places. It is nevertheless the variance per point when points are considered in pairs. As a function of $\mathbf{h}$ it is the semivariogram, now usually termed simply the variogram.

For second-order stationary processes the variogram and the covariance function of $\mathbf{h}$ are equivalent:

$$\gamma(\mathbf{h}) = C(0) - C(\mathbf{h}), \quad (9)$$

and

$$\gamma(\mathbf{h}) = \sigma^2 \{1 - \rho(\mathbf{h})\}. \quad (10)$$

Estimating the variogram

Semivariances can be, and usually are, estimated from data, $z(\mathbf{x}_1), z(\mathbf{x}_2), \dots$, by the method of moments:

$$\hat{\gamma}(\mathbf{h}) = \frac{1}{2m(\mathbf{h})} \sum_{i=1}^{m(\mathbf{h})} \{z(\mathbf{x}_i) - z(\mathbf{x}_i + \mathbf{h})\}^2, \quad (11)$$

in which $m(\mathbf{h})$ is the number of paired comparisons at lag $\mathbf{h}$. By changing $\mathbf{h}$ one obtains an ordered set, an experimental variogram, which can be displayed as a graph of $\hat{\gamma}$ against $\mathbf{h}$. Fig. 2 shows examples in which the experimental semivariances for the data in Fig. 1 are plotted as points against the lag distance, $h = |\mathbf{h}|$, for the one-dimensional transect. Where sampling is at regular intervals along a transect then it is natural to increment the lag in steps of one sampling interval. For a grid one may compute $\hat{\gamma}$ itself on a grid. Where the sampling points are irregularly scattered the actual separations must be placed into ‘bins’ with limits in separating distance and also in direction if there is more than one dimension—see Fig. 3. Gridded data may be treated similarly.

Fig. 2 Experimental variograms of clay content of soil estimated by the method of moments and spherical models fitted to them; (A) topsoil and (B) subsoil.

Fig. 3 Discretization of the lag in two dimensions for irregularly scattered data. All separations within the grey sector are assigned to lag distance h and direction θ .

Fig. 4 Four kinds of bounded variogram: (A) spherical, (B) exponential, (C) stable function with $a = 1.75$, (D) Whittle function.

Robust estimators

Outliers and other exceptional values in the tails of distributions can carry undue weight in the estimation of semivariances. To counteract such effects robust estimators may be used. Three enjoy some popularity; they go by the names of their inventors: Cressie and Hawkins (1980), Dowd (1984), and Genton (1998). Webster and Oliver (2007) give the definitions and compare their merits; they found none to be best in all circumstances.

Models for variograms

Values of $\mathbf{h}$ define discrete points on the experimental variogram. Estimates computed by Eq. (11) at those points are more or less in error, arising from the sampling, and the sequences tend to fluctuate from point to point erratically also. The underlying variogram, Eq. (8), is a continuous function in as many dimensions as the variable $Z(\mathbf{x})$. Obtaining such a function from an experimental variogram involves a further kind of modelling; it requires one to fit a plausible function to the experimental values. The usual approach is to fit the simplest model that makes sense.

Fig. 4A shows the principal features of many, if not most, experimental variograms. They are as follows.

1. The variance increases from near the ordinate with increasing lag distance.
2. It reaches a maximum at which it remains thereafter.
3. Any simple smooth line or surface placed through the points and projected to the ordinate cuts it at some value greater than 0.

The model must also be mathematically acceptable in that it cannot give rise to 'negative variances' when random variables are combined. Let $z(\mathbf{x}_i)$, $i = 1, 2, \dots, n$, be a realization of the random variable $Z(\mathbf{x})$ with covariance function $C(\mathbf{h})$ and variogram $\gamma(\mathbf{h})$, and consider the linear sum

$$y = \sum_{i=1}^n \lambda_i z(\mathbf{x}_i), \quad (12)$$

where the λ_i are any arbitrary weights. The variable Y from which y derives is also a random variable, and its variance is given by

$$\text{var}[Y] = \sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j C(\mathbf{x}_i - \mathbf{x}_j), \quad (13)$$

where $C(\mathbf{x}_i - \mathbf{x}_j)$ is the covariance of Z between $\mathbf{x}_i$ and $\mathbf{x}_j$. This variance must be positive or zero; it may not be negative. If $Z(\mathbf{x})$ is intrinsic only then the covariances do not exist, and one must re-write Eq. (13) as

$$\text{var}[Y] = C(0) \sum_{i=1}^n \lambda_i \sum_{j=1}^n \lambda_j - \sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j \gamma(\mathbf{x}_i - \mathbf{x}_j), \quad (14)$$

where $\gamma(\mathbf{x}_i - \mathbf{x}_j)$ is the semivariance of Z between $\mathbf{x}_i$ and $\mathbf{x}_j$. The first term on the right-hand side of this equation is eliminated if the weights sum to 0, and one is left with

$$\text{var}[Y] = - \sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j \gamma(\mathbf{x}_i - \mathbf{x}_j). \quad (15)$$

This too must guarantee non-negative variances, and only functions that do that are admissible. They are said to be conditional negative semi-definite, CNSD, the condition being that the weights in Eq. (15) sum to zero.

There are only a few families of simple functions that satisfy the above criteria. They can be divided into those that are bounded and those that are not. In the first group are the popular spherical and exponential models. Their formulae in their isotropic forms, i.e. for $h = |\mathbf{h}|$, are as follows.

Spherical

The spherical function has the following equation:

$$\begin{aligned} \gamma(h) &= c_0 + c_1 \left\{ \frac{3h}{2r} - \frac{1}{2} \left(\frac{h}{r} \right)^3 \right\} \quad \text{for } 0 < h \leq r \\ &= c_0 + c_1 \quad \text{for } h > r \\ &= 0 \quad \text{for } h = 0. \end{aligned} \quad (16)$$

Here $\gamma(h)$ is the semivariance at lag h , and c_1 is the a priori variance of the autocorrelated process. The quantity c_0 is the intercept on the ordinate, and is known as the *nugget variance*, a term deriving from gold mining. The combined $c_0 + c_1$ is known as the *sill* of the model, and c_1 is the sill of the correlated variance. These quantities are illustrated in Fig. 4A, and Fig. 2B shows the function fitted to the experimental variogram of subsoil clay content, Fig. 1B. The values of the parameters c_0 , c_1 , and r are listed in Table 3.

The function has a finite distance parameter, r ; this is its *range*, also known as its correlation range. It marks the limit of spatial dependence; values at places closer to one another than it are more or less correlated, whereas those further apart are not. It implies that all the variance in $\mathcal{R}$ is encountered within that distance, and in this sense it corresponds to the concept of the representative elementary volume (REV).

The function gets its name from the formula for the volume of two intersecting spheres, which are of diameter r .

The semivariance at lag 0 is itself zero, and for continuous processes such as most physical and chemical properties of the soil $\gamma(h)$ should increase gradually as h increases from 0. In practice, we usually lack sufficient estimates of $\gamma(h)$ near the ordinate to fit a model through the origin, and we therefore take the conservative approach above. The nugget variance is therefore best regarded as embodying variation within the shortest sampling interval plus any measurement error.

Other functions with the same general form and finite ranges are the bounded linear function (valid in one dimension only), the circular (valid in one and two dimensions but not in three), and the pentaspherical.

Exponential

The equation for the exponential function is

$$\begin{aligned} \gamma(h) &= c_0 + c_1 \left\{ 1 - \exp\left(-\frac{h}{a}\right) \right\}, \text{ for } h > 0 \\ &= 0 \text{ for } h = 0 \end{aligned} \quad (17)$$

in which c_0 and c_1 have the same meanings as before, but now with a distance parameter, a . The exponential model approaches its sill asymptotically and has no definite range therefore. A working range is often taken as $a' = 3a$ at which point the function has reached 95% of c_1 . This model is illustrated in Fig. 4B.

Models with reverse curvature near the origin

Some variograms approach the origin with decreasing gradients. They arise from smoother variation over short distances than do the spherical and exponential functions. They may be described by the general equation:

$$\gamma(h) = c \left\{ 1 - \exp\left(-\frac{h^2}{a^2}\right) \right\}, \quad (18)$$

in which $0 < \alpha \leq 2$. If $\alpha = 2$ Eq. (18) is that of the Gaussian function. This is at the limit of acceptability and gives rise to unstable prediction—see Wackernagel (2003) for an example and discussion. It is best replaced by stable models with $\alpha < 2$. Fig. 4C with $\alpha = 1.75$ is an example.

The Gaussian function is one of another family of models, namely the Matérn functions, which have become increasingly popular recently. The equation is

$$\gamma(h) = c \left\{ 1 - \frac{1}{2^{v-1} \Gamma(v)} \left(-\frac{h}{a} \right)^v K_v \left(\frac{h}{a} \right) \right\}. \quad (19)$$

Here c is the sill variance and a is a distance parameter, as before. The equation embodies the gamma function, Γ , with parameter v and the Bessel function of the second kind, K_v , for parameter v . Parameter v describes the smoothness of variation and can vary from 0 (very rough) to infinity (very smooth). It includes as special cases the exponential function when $v = 0.5$, Whittle's elementary correlation when $v = 1$ (below) and the Gaussian function when $v = \infty$.

The attraction of Whittle's function is that it derives theoretically from diffusion in two dimensions. Its equation is

$$\gamma(h) = c \left\{ 1 - \frac{h}{a} K_1 \left(\frac{h}{a} \right) \right\}, \quad (20)$$

in which a is again a distance parameter, and K_1 is the modified Bessel function of the second kind—see Fig. 4D. To all can be added a nugget variance, c_0 , if desired.

Unbounded models

Variograms of processes that are intrinsic but not second-order stationary increase without bound as the lag distance increases. These can usually be fitted by power functions, for which the general equation including a nugget is

$$\gamma(h) = c_0 + qh^b. \quad (21)$$

The parameter q describes the intensity of the process, and the exponent, which must lie strictly between 0 and 2 (these limits are excluded), describes the curvature. If $b < 1$ then the curve is convex upwards, if it is 1 then the increase in variance with distance is strictly linear, and if $b > 1$ then the curve is concave upwards. The curve with $b = 2$ is a parabola and describes a smoothly continuous process that is not random. Fig. 5 illustrates the curves for several values of b .

Anisotropy

The variogram of a two-dimensional process is itself two-dimensional, and if the process is anisotropic then so is its variogram, which is then a function of both distance, h and direction, θ . In the simplest cases the anisotropy is geometric, meaning that it can be made isotropic by a linear transformation of the coordinates. The transformation is defined by reference to an ellipse:

$$\Omega(\theta) = \sqrt{A^2 \cos^2(\theta - \varphi) + B^2 \sin^2(\theta - \varphi)}, \quad (22)$$

Fig. 5 Four valid power functions, Eq. (21) with exponents, b , 0.2, 0.5, 1.0 and 1.5, plus the inadmissible limiting function with $b = 2$.

Fig. 6 Ellipse showing parameters of geometric anisotropy.

Fig. 7 Perspective diagram of the variogram surface of an anisotropic spherical function.

where A and B are the long and short diameters, respectively, of the ellipse, and φ is its orientation, i.e. the direction of the long axis; see Fig. 6. Eq. (22) is incorporated into the models as follows. For the bounded models Ω replaces the distance parameter of the isotropic variogram. So, for example, in the exponential

$$\gamma(h, \theta) = c_0 + c \left\{ 1 - \exp \left(-\frac{h}{\Omega(\theta)} \right) \right\}, \quad (23)$$

and in the linear function:

$$\gamma(h, \theta) = c_0 + \Omega(\theta)h^\alpha, \quad (24)$$

in which $\alpha = 1$. Fig. 7 shows an anisotropic spherical function. Notice how the range of the model changes with changing direction.

Fitting the models

As above, experimental variograms computed by the method of moments fluctuate more or less erratically. Any of the models represented by Eqs. (16)–(24) must be fitted to them. All have non-linear parameters, and these must be found by numerical approximation, preferably accompanied by visual inspection to ensure that the models are plausible. The individual semivariances may be weighted in proportion to the numbers of paired comparisons from which they are computed or some other function of those numbers. Finally, any chosen model may be checked by cross-validation. In this technique, each datum in turn is predicted from other data in its neighborhood by ordinary punctual kriging (see below), and the squared difference between it and its prediction is compared with its kriging variance, $\sigma_K^2(\mathbf{x}_0)$. Ideally the two should be equal. Thus, if the datum is denoted $z(\mathbf{x}_0)$ and its prediction $\hat{Z}(\mathbf{x}_0)$ then the ratio $\left\{ \hat{Z}(\mathbf{x}_0) - z(\mathbf{x}_0) \right\}^2 / \sigma_K^2(\mathbf{x}_0)$ should equal 1.0. The most suitable model might be the one for which the mean of this ratio is closest to 1.0. This ratio is variously known as the mean squared deviation ratio and the mean standardized deviation. If the variable z has a normal (Gaussian) distribution then this ratio has a skewed distribution for which the median is 0.455, and one may judge the goodness of a model for its closeness to this value.

The above procedures based on the method-of-moments or robust alternatives and subsequent non-linear least squares fitting are not the only ones for modelling variograms. Likelihood methods and specifically residual maximum likelihood (REML) are feasible for moderately large sets of data. They come into their own where there is geographic trend or correlation with other variables, and their role is dealt with in the next section.

Combining trend and random fluctuation

The above functions describe processes that are entirely random though correlated. In accord with Matheron's intrinsic hypothesis they can be represented by the model:

$$Z(\mathbf{x}) = \mu_V + \varepsilon(\mathbf{x}), \quad (25)$$

in which μ_V is the mean, i.e. constant, in some neighborhood V , and $\varepsilon(\mathbf{x})$ is the autocorrelated random variable as defined in Eq. (8). It often happens that such models are unacceptable, either because there is evident long-range trend across a region or because over short distances the variation appears smooth. In these circumstances μ_V cannot be treated as constant but must be replaced by a deterministic term, such as $u(\mathbf{x})$ in Eq. (1) and which depends on the position $\mathbf{x}$. Recall that the model is

$$Z(\mathbf{x}) = u(\mathbf{x}) + \varepsilon(\mathbf{x}).$$

If $u(\mathbf{x})$ can describe the variation over the whole of $\mathcal{R}$ simply then it tends to be called trend. If it is local only then it is more often called 'drift'. These terms are not strictly defined and are often used interchangeably. In either event $u(\mathbf{x})$ is usually represented by a low-order polynomial, so that Eq. (1) becomes

$$Z(\mathbf{x}) = \sum_{j=0}^J \beta_j f_j(\mathbf{x}) + \varepsilon(\mathbf{x}), \quad (26)$$

in which the β_j are unknown coefficients and the $f_j(\mathbf{x})$ are known functions of our choosing.

It is fairly easy, even if somewhat arbitrary, to separate any long-range trend from the short-range apparently random fluctuation, and to estimate the parameters of the two components separately. This is the basis of the technique known as regression kriging. Its shortcoming is that variograms, which are of the residuals from the estimated trends, are biased, and kriging variances (see below) are underestimated. It is not at all easy to do it where there is short-range drift. Early attempts to deal with these circumstances involved a structural analysis, which was effectively a process of trial-and-error. More recently they have been replaced by likelihood methods and specifically residual maximum likelihood (REML) in which the parameters of the variogram and the coefficients of the trend are estimated simultaneously.

Residual maximum likelihood estimation

In the simplest case of a linear trend in two dimensions Eq. (26) expands to

$$Z(\mathbf{x}) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \varepsilon(\mathbf{x}). \quad (27)$$

More generally and in matrix form the trend model is

$$Z(\mathbf{x}) = \mathbf{w}\boldsymbol{\beta} + \varepsilon(\mathbf{x}), \quad (28)$$

in which the vector $\mathbf{w}$ with $J + 1$ columns contains the $J + 1$ elements $1, x_1, x_2, \dots, x_J$ of the trend, and the vector $\boldsymbol{\beta}$ contains the coefficients. This is the linear mixed model. Data from a survey can be represented similarly:

$$\mathbf{z}(\mathbf{X}_d) = \mathbf{W}_d \boldsymbol{\beta} + \varepsilon(\mathbf{X}_d), \quad (29)$$

in which $\mathbf{z}(\mathbf{X}_d)$ with n rows is the vector of observed values at the corresponding set of points denoted by $\mathbf{X}_d$. Matrix $\mathbf{W}_d$ with n rows and $J + 1$ columns replaces the vector $\mathbf{w}$ of Eq. (28) and is called the 'design matrix'. The residuals $\varepsilon(\mathbf{X}_d)$ are assumed to be second-order stationary random variables jointly normally distributed with zero means and $n \times n$ covariance matrix $\mathbf{C}_d$. Being second-order stationary they have their equivalents in the variogram:

$$C(\mathbf{h}) = C(\mathbf{0}) - \gamma(\mathbf{h}).$$

Parameters for a plausible model are found by maximization of the likelihood of the residuals given the data, $L[\boldsymbol{\theta} | \mathbf{z}(\mathbf{X}_d)]$, in which the vector $\boldsymbol{\theta}$ is short-hand for the parameters of the variogram. For the spherical model, for example, $\boldsymbol{\theta} \equiv \{c_0, c_1, r\}$. The values of these parameters that maximize the likelihood are found numerically, and they are the ones that define the variogram of the residuals. Lark et al. (2006) and Webster and Oliver (2007) give the derivation of the equations in full. From those values one computes the covariance matrix $\mathbf{C}_d$ for the data points, and from it estimates the coefficients in $\boldsymbol{\beta}$:

$$\hat{\boldsymbol{\beta}} = \left(\mathbf{W}_d^T \hat{\mathbf{C}}_d^{-1} \mathbf{W}_d \right)^{-1} \mathbf{W}_d^T \hat{\mathbf{C}}_d^{-1} \mathbf{z}(\mathbf{X}_d) \quad (30)$$

Classification as external drift

For many years pedologists dealt with spatial variation by classification and drew boundaries between the classes when mapping them to produce what are technically called choropleth maps. In landscapes where the soil changes from one type to another fairly

Table 2 Means of subsoil clay percentage in the classes of soil over nine geological strata as estimated by ordinary least squares and REML analysis.

<i>Raw data</i>		
Mean		39.1
Median		36.0
Variance		936.81
<i>Class</i>	<i>Mean</i>	
	<i>OLS estimate</i>	<i>REML estimate</i>
Sharp's Hill Beds (clay)	61.3	75.4
Great Oolite	33.4	42.3
Lower Estuarine Beds (silt)	12.9	15.1
Chipping Norton Limestone (limestone)	9.5	10.8
Chipping Norton Limestone (sand)	15.1	25.2
Upper Lias (clay)	69.9	50.3
Pleistocene and Recent (silt and clay)	55.8	51.0
Middle Lias (ironstone)	41.4	43.4
Middle and Lower Lias (clay)	68.6	67.5

abruptly, as where it overlies boundaries between rock types, the practice has merit. Between the boundaries, however, the soil tends to vary in a more continuous spatially correlated apparently random way. The latter accords with the basic geostatistical model; classifications in contrast are fixed effects created by the pedologists. One might treat the two sources of variation separately by sampling to a random design to estimate class means, and characterize the variation within classes by variograms of the residuals from the class means. As above, that would be inefficient for mapping variation within the classes. Further, a pedologist might not know how to classify the soil sensibly until after examining survey data. The pedologist is thus typically faced with estimating class means without bias from non-random sampling and variograms of the residuals from those means. The geostatistical solution to this problem is to treat a classification as an external drift and to combine it with the apparently random variation within the classes in a single analysis of a mixed model by REML.

The data on the clay content of the subsoil along the Sandford transect displayed in Fig. 1B illustrate the solution. The transect lies across nine Jurassic geological strata in Mid-Oxfordshire, England. The figure shows some fairly sharp changes in clay content, and these correspond to boundaries between the outcrops of the rock strata. Table 2 summarizes the data overall and for the classes individually. For illustrative purposes the means calculated by ordinary least squares (OLS) are listed along with the REML estimates. Fig. 8 repeats the variogram of the raw data, shown in Fig. 2B, as the uppermost sequence of points and fitted spherical model. The lowest sequence of points in the figure is the experimental variogram of the OLS residuals with its fitted curve, also spherical. The curve in the middle is the variogram of the REML residuals from the class means as is that of the exponential model. Table 3 lists the fitting parameters.

The example shows how soil classification can affect the outcome of a geostatistical analysis and the importance of mixed modelling where data are from systematic samples. Ordinary least squares estimates of class means are evidently biased, and the variances of the residuals underestimate the true variances. The variograms over short lag distances are remarkably similar over short lag distances; as the distance increases so the variogram of the residuals from the OLS estimates departs from the best variogram based on the mixed model. Cressie (1993) forecasts exactly this behavior.

Coregionalization—simultaneous variation in two or more variables

Any two variables, say z_u and z_v , may be correlated and in particular linearly correlated. That relation is conventionally expressed by the product-moment correlation coefficient:

$$\rho = \frac{\text{cov}[uv]}{\sqrt{\text{var}[u] \times \text{var}[v]}}, \quad (31)$$

i.e. the covariance of z_u and z_v divided by the product of their standard deviations.

The two spatial random variables, $Z_u(\mathbf{x})$ and $Z_v(\mathbf{x})$, may also be *spatially* intercorrelated in that each is spatially correlated both with itself, i.e. autocorrelated, and with the other. The two variables are then said to be cross correlated. In these circumstances the two variables have autovariograms, one each, as defined by Eq. (8) and for present purposes denoted $\gamma_{uu}(\mathbf{h})$ and $\gamma_{vv}(\mathbf{h})$. They also have a cross-variogram, $\gamma_{uv}(\mathbf{h})$, defined by

Fig. 8 Variograms of clay content of the subsoil along the transect shown in Fig. 1B; top of raw data, bottom of OLS residuals, and middle REML estimate from mixed model. Parameter estimates are listed in Table 3.

Table 3 Variogram models and their parameters of Eqs. (16) and (17) of subsoil clay on the Sandford transect, Fig. 1B.

Source	Spherical			Exponential		
	c_0	c_1	r/m	c_0	c_1	a/m
Raw data	120.6	580.3	207.0			
OLS residuals	108.4	296.4	79.2			
REML residuals				77.5	505.3	67.3

$$\gamma_{uv}(\mathbf{h}) = \frac{1}{2} E[\{Z_u(\mathbf{x}) - Z_u(\mathbf{x} + \mathbf{h})\} \{Z_v(\mathbf{x}) - Z_v(\mathbf{x} + \mathbf{h})\}]. \quad (32)$$

If both variables are second-order stationary with means μ_u and μ_v then both will have covariance functions, C_{uu} and C_{vv} , as defined in Eq. (5), and a cross-covariance:

$$C_{uv}(\mathbf{h}) = E[\{Z_u(\mathbf{x}) - \mu_u\} \{Z_v(\mathbf{x} + \mathbf{h}) - \mu_v\}]. \quad (33)$$

There is also a cross-correlation coefficient, ρ_{uv} , given by

$$\rho_{uv}(\mathbf{h}) = \frac{C_{uv}}{\sqrt{C_{uu}(\mathbf{0})C_{vv}(\mathbf{0})}}. \quad (34)$$

This is effectively the extension of the Pearson product-moment correlation coefficient of Eq. (31) into the spatial domain, and when $\mathbf{h} = \mathbf{0}$ it is the Pearson coefficient.

The cross-covariance is in general not symmetric, i.e.

$$E[\{Z_u(\mathbf{x}) - \mu_u\} \{Z_v(\mathbf{x} + \mathbf{h}) - \mu_v\}] \neq E[\{Z_v(\mathbf{x}) - \mu_v\} \{Z_u(\mathbf{x} + \mathbf{h}) - \mu_u\}]. \quad (35)$$

In words, the cross-covariance between $Z_u(\mathbf{x})$ and $Z_v(\mathbf{x})$ in one direction is different from that in the other, or expressed another way

$$C_{uv}(\mathbf{h}) \neq C_{uv}(-\mathbf{h}) \quad \text{or equivalently} \quad C_{uv}(\mathbf{h}) \neq C_{uv}(\mathbf{h}), \quad (36)$$

since

$$C_{uv}(\mathbf{h}) = C_{vu}(-\mathbf{h}).$$

One can envisage asymmetry between two soil properties at different depths on a slope as result of creep or solifluction. The subsoil will tend to lag behind the topsoil. Similarly, irrigation by flooding always from the same end of a field might distribute salts differentially in the direction of flow. Asymmetric covariances have not been reported in the soil literature as far as I know, however.

The cross-variogram and the cross-covariance function (if it exists) are related by

$$\gamma_{uv}(\mathbf{h}) = C_{uv}(\mathbf{0}) - \frac{1}{2}\{C_{uv}(-\mathbf{h}) + C_{uv}(\mathbf{h})\}, \quad (37)$$

This quantity contains both $C_{uv}(\mathbf{h})$ and $C_{uv}(-\mathbf{h})$ and in consequence loses any information on asymmetry; it is an even function, i.e. symmetric:

$$\gamma_{uv}(\mathbf{h}) = \gamma_{vu}(\mathbf{h}) \quad \text{for all } \mathbf{h}.$$

One can estimate cross-semivariances in a way similar to that of the auto-semivariances:

$$\hat{\gamma}_{uv}(\mathbf{h}) = \frac{1}{2m(\mathbf{h})} \sum_{i=1}^{m(\mathbf{h})} \{z_u(\mathbf{x}_i) - z_u(\mathbf{x} + \mathbf{h})\} \{z_v(\mathbf{x}_i) - z_v(\mathbf{x} + \mathbf{h})\}, \quad (38)$$

and form the sample cross-variogram by simply incrementing $\mathbf{h}$. There is an equivalent formula for computing the cross-covariances. Notice that there must be numerous places where both z_u and z_v have been measured.

Modelling the coregionalization

The cross-variogram can be modelled in the same way as the auto-variogram, and the same restricted set of functions is available. There is one additional constraint. Any linear combination of the variables is itself a regionalized variable, and its variance cannot be negative. This is assured by adoption of the *linear model of coregionalization*. In it the variable, $Z_u(\mathbf{x})$, is assumed to be the sum of independent (orthogonal) random variables, $Y_j^k(\mathbf{x})$:

$$Z(\mathbf{x}) = \sum_{k=1}^K \sum_{j=1}^k a_{uj}^k Y_j^k(\mathbf{x}) + \mu_u, \quad (39)$$

in which the superscript k is an index, not a power. There is a similar assumption for $Z_v(\mathbf{x})$. If the assumptions hold then the pair of variables has a cross-variogram

$$\gamma_{uv}(\mathbf{h}) = \sum_{k=1}^K \sum_{j=1}^k a_{uj}^k a_{vj}^k g^k(\mathbf{h}). \quad (40)$$

The products in the second summation can be replaced by b_{uv}^k to give

$$\gamma_{uv}(\mathbf{h}) = \sum_{k=1}^K b_{uv}^k g^k(\mathbf{h}). \quad (41)$$

The quantities are the variances and covariances, e.g. nugget and sill variances, for the independent components of a spherical model. For two variables there are the three nugget variances, b_{uu}^1 , b_{vv}^1 and b_{uv}^1 and similarly three for the sills of the correlated variances. The coefficients $b_{uv}^k = b_{vu}^k$ for all k , and for each k the matrix of coefficients

$$\begin{bmatrix} b_{uu}^k & b_{uv}^k \\ b_{vu}^k & b_{vv}^k \end{bmatrix}$$

must be positive definite. Since the matrix is symmetric it is sufficient that $b_{uu}^k > 0$ and $b_{vv}^k \geq 0$ and that its determinant is positive or zero:

$$|b_{uv}^k| = |b_{vu}^k| \leq \sqrt{b_{uu}^k b_{vv}^k}. \quad (42)$$

This is Schwarz's inequality.

Any number of regionalized variables may be embodied in the linear model of coregionalization. If there are V of them then the full matrix of coefficients, $[b_{ij}]$, will be of order V , and its determinant and all its principal minors must be positive or zero.

Schwarz's inequality has the following consequences.

1. Every basic structure, $g^k(\mathbf{h})$, present in the cross-variogram must also appear in the two auto-variograms, i.e. $b_{uu}^k \neq 0$ and $b_{vv}^k \neq 0$ if $b_{uv}^k \neq 0$. As a corollary, if a basic structure $g^k(\mathbf{h})$ is absent from either auto-variogram then it may not be included in the cross-variogram.
2. Structures may be present in the auto-variograms without their appearing in the cross-variogram, i.e. b_{uv}^k may be zero when $b_{uu}^k > 0$ and $b_{vv}^k > 0$.

Parameters of the linear model of the coregionalization with the above constraints can be fitted by iteration. The distance parameters are usually first approximated by the fitting of models independently to the experimental variograms, and good compromise values are chosen from these. Then with those values fixed the values of the b_{uv}^k are found to minimize the sums of the squares of the residuals, subject to the condition that the solution guarantees non-negative variances, i.e. is CNSD. One may check the validity of the resulting model by plotting it on a graph of the experimental cross-semivariances plus the limiting values that would hold if the correlation between the variables were perfect. These limits constitute the hull of perfect correlation, which is obtained from the coefficients b_{uu}^k and b_{vv}^k by

$$\text{hull} [\gamma(\mathbf{h})] = \pm \sum_{k=1}^K \sqrt{b_{uu}^k b_{vv}^k} g^k(\mathbf{h}).$$

The line should fit close to the experimental values for the model. It must also fall within the hull to be acceptable. If it lies close to the hull then the cross-correlation is strong; if in contrast it is far from the bounds then the cross-correlation is weak. [Wackernagel \(2003\)](#) describes this aspect of coregionalization well.

Example

The clay content of the subsoil was recorded at the same sampling points as those for topsoil in [Fig. 1B](#), and in combination with the topsoil data illustrate the coregionalization. [Table 1](#) contains a summary, and it includes the Pearson correlation coefficient, which is 0.59, indicating a modest correlation overall. The experimental auto-variograms for the two depths together with their cross-variogram are shown in [Fig. 9](#) by the black discs. Spherical models can be fitted to all of them with ranges varying between 191 and 265 m, with an average of 228 m. If this value is fixed for the coregionalization model then the nugget and sill component components of the model are obtained as described above and appear in [Table 4](#). They are somewhat different from those fitted independently, but only somewhat. The final result is shown in [Fig. 9](#) by the solid lines through the plotted points. The model evidently fits well.

Fig. 9 Auto- and cross-variograms of clay content in topsoil and subsoil with the linear model of coregionalization fitted. The dashed lines depict the hull of perfect correlation.

Table 4 Fitted nugget and sill variances of the correlated structure, i.e. the coefficients b_{uv}^k of Eq. (41), of the spherical model of coregionalization of clay in topsoil and subsoil with a range of 228 m.

		Topsoil	Subsoil
Nugget variance	Topsoil	17.841	
	Subsoil	−0.799	167.986
Sill variance	Topsoil	178.659	
	Subsoil	211.436	509.723

The dashed lines on the graph for Subsoil $\times$ Topsoil define the hull of perfect correlation. The cross-variogram falls within the hull, as it should, and the moderate distance it keeps from the upper bound is a measure of moderate cross-correlation over the lag distances computed.

Spatial prediction—kriging

Ordinary kriging

The variogram and covariance functions are not only elegant mathematical descriptions of the real world of the soil, they are crucial for local estimation, or spatial prediction as it is better called, by kriging.

Kriging is a general term for processes of weighted averaging of data to provide unbiased local estimates of unknown values of a variable with minimum variance. In the simplest case for a place $\mathbf{x}_0$ where the mean is unknown (the usual situation) the estimate is formed as

$$\hat{Z}(\mathbf{x}_0) = \sum_{i=1}^N \lambda_i z(\mathbf{x}_i), \quad (43)$$

where the $z(\mathbf{x}_i)$, $i = 1, 2, \dots, N$ are sample data at places $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N$, and the λ_i are weights. The weights sum to 1 to assure unbiasedness, i.e. $\sum_{i=1}^N \lambda_i = 1$, and the variance of the estimate is given by

$$\begin{aligned} \sigma^2 Z(\mathbf{x}_0) &= E \left[\left\{ \hat{Z}(\mathbf{x}_0) - z(\mathbf{x}_0) \right\}^2 \right] \\ &= 2 \sum_{i=1}^N \lambda_i \gamma(\mathbf{x}_i, \mathbf{x}_0) - \sum_{i=1}^N \sum_{j=1}^N \lambda_i \lambda_j \gamma(\mathbf{x}_i, \mathbf{x}_j). \end{aligned} \quad (44)$$

Here $\gamma(\mathbf{x}_i, \mathbf{x}_j)$ is the semivariance between the data points $\mathbf{x}_i$ and $\mathbf{x}_j$, and $\gamma(\mathbf{x}_i, \mathbf{x}_0)$ is the semivariance between the data point $\mathbf{x}_i$ and the target point $\mathbf{x}_0$.

This variance is minimized by solution of the $N + 1$ equations:

$$\begin{aligned} \sum_{i=1}^N \lambda_i \gamma(\mathbf{x}_i, \mathbf{x}_j) + \psi(\mathbf{x}_0) &= \gamma(\mathbf{x}_i, \mathbf{x}_j) \quad \forall j \\ \sum_{i=1}^N \lambda_i &= 1, \end{aligned} \quad (45)$$

in which the $\psi(\mathbf{x}_0)$ is a Lagrange multiplier introduced for the minimization. The solution yields the optimum weights, and these are inserted into Eq. (43) to give the required estimate at $\mathbf{x}_0$.

The minimized variance is also obtained from the solution as

$$\sigma_{OK}^2(\mathbf{x}_0) = \sum_{i=1}^N \lambda_i \gamma(\mathbf{x}_i, \mathbf{x}_0) + \psi(\mathbf{x}_0). \quad (46)$$

This particular form of the technique is ordinary punctual kriging—ordinary because it is the most used, and punctual because the estimates are for points of the same size and shape, i.e. the same *supports*, as the bodies of soil or other material on which the measurements were made. It is readily generalized for estimating blocks, B , larger than the supports of the data. Eq. (43) holds for the averaging, though with B replacing $\mathbf{x}_0$. In Eq. (45) the individual semivariances on the right-hand sides are replaced by the averages of the semivariances between the data points and the target block, B , $\bar{\gamma}(\mathbf{x}_i, B)$. Finally, the kriging variance is given by

$$\sigma_{OK}^2(B) = \sum_{i=1}^N \lambda_i \bar{\gamma}(\mathbf{x}_i, B) + \psi(B) - \bar{\gamma}(B, B), \quad (47)$$

where $\bar{\gamma}(B, B)$ is the average semivariance within B , i.e. the within-block variance.

When the kriging equations are solved it usually turns out that only the few points nearest to the target point or block carry any appreciable weight; the weights of the others are so close to 0 that they can be ignored. Kriging is thus a local weighted average. It has two other intuitively attractive features.

1. Where data points are clustered the weight of the cluster is divided among its members so that the individual weights are small compared with those of isolated points.
2. Data points lying approximately in a line between the target and more distant points screen the latter, which tend as a result to have virtually no weight, however close they are to the target.

This also has practical implications. The kriging systems, Eq. (45), need never be large. They are swiftly solved, and instabilities with matrix inversion are rare.

It is now evident why the variogram, or the equivalent covariance function, is so important; the kriging systems need values drawn from it. As above, these must not give rise to negative kriging variances, and so a valid function must be fitted to the experimental variogram.

Ordinary kriging will serve in some 90% of cases; it is the 'work horse' of practical geostatistics. It requires the fewest assumptions and the least knowledge. It has been much used to map soil properties, including concentrations of plant nutrients, salinity, trace element contents, pollutants and nematode infestation. The kriging systems are solved at close intervals on a grid, from which isarithms, 'contours,' of the estimates can be drawn by other graphics programs. This has led to its application in land reclamation and precision agriculture. The kriging variances can be mapped similarly; patches of large variance coincide with sparse sampling, and so the maps can show where denser sampling is necessary or desirable to achieve more reliable estimates.

Cokriging

Ordinary cokriging is an extension of ordinary autokriging, in which the semivariances of both the target variable and those of the subsidiary variable(s), the u and v , are drawn from the model of coregionalization, Eq. (41). Where a target variable is sampled less intensely than the subsidiary variable(s) cokriging adds spatial information and diminishes the kriging prediction variances. That is its principal merit. Where the target variable and subsidiary variable(s) are sampled at the same places, i.e. full sampling, cokriging gives the same or almost the same results as ordinary kriging of the target variable alone. Its merit then is coherence when two or more target variables are predicted from the same systems. One of the best examples of this application was for the prediction of the depths of the Upper Chalk beneath the English Channel before the rail tunnels were bored in the 1990s (Chilès and Delfiner, 2012).

Other forms of kriging

Although ordinary kriging is by far the most popular application of geostatistics in soil science there are situations in which it falls short, either by failing to take into account what is already known or because it needs taking beyond mere predictions of measured variables. There are numerous elaborations of the technique; two groups are mentioned below.

Universal kriging and kriging with external drift

Universal kriging takes into account known or estimated trend in the target variable. The underlying model is that of Eq. (26), usually with a simple low-order polynomial for the trend as in Eq. (26). The variogram of the residuals from the trend, estimated best nowadays by REML as described above, is combined with the function for trend to predict the target variable. The fixed effects of subsidiary variables, external drifts, are taken into account similarly by the combination of them and the variograms of the residuals from those drifts.

Indicator and disjunctive kriging

Authorities responsible for controlling infestation by pests and pollution, for restoring contaminated land and restricting its use set limits on the relevant variables. They then need to estimate the probabilities that these threshold values are exceeded (or not). One technique for this is indicator kriging in which the scale of a variable is divided into two or more classes each of which is modelled and kriged. Goovaerts (1997) describes the procedure fully. A more elaborate and sounder technique is disjunctive kriging. It transforms data of almost any frequency distribution to normal (Gaussian) via Hermite polynomials. The probabilities of a variable's exceeding specified thresholds are then estimated from the normal distribution—see Webster and Oliver (2007) for details.

Applications and new developments

In the two decades 1980–2000 pedometricians mastered geostatistics and adapted it to soil survey. Since then software for its implementation, especially that embodied in geographic information systems, has enabled pedologists, agronomists, environmental scientists and land managers to apply the techniques in a wide variety of situations in many parts of the world. Most have involved mapping, which is covered in the chapter on pedometrics. Insert the words 'soil' and 'kriging' into the Web of Science and

you will find more than 5000 published journal articles. Add the word ‘mapping’ and that will still produce more than 2700 articles. There are undoubtedly thousands more cases, published and unpublished, for specific projects. The attractions of unbiased predictions with minimum and known variances are compelling.

Many recent articles report straightforward applications for mapping plant nutrients, as that by Tamburi et al. (2021), for salinity control (Shaddad et al., 2020; Li et al., 2015) and organic carbon (Boubehziz et al., 2020). Many other applications concern pollutants; for example, both Kebonye et al. (2021) and Jia et al. (2021) analyzed and mapped arsenic in polluted soil. Remotely sensed data are increasingly being combined with measurements on the soil to enhance prediction either by cokriging (e.g. Shahriari et al., 2019) or with external drift.

Machine learning is also being combined with kriging (see the separate chapter on machine learning). Jia et al. (2021), for example, gathered images of the soil surface by a drone and used machine learning and kriging for their mapping. They also used simulation, another widespread geostatistical technique, to assess the uncertainties of their predictions. Szabo et al. (2019) used random forests and geostatistics to map some of the soil’s hydraulic properties, and Orton et al. (2020) combined machine learning with geostatistics to model and map soil properties in three dimensions. Fentanes et al. (2020) ventured further by combining kriging with data from a robotic cosmic-ray sensor.

Abstract

Information on the soil of any region is never free of error because it is derived from imperfect measurements, imperfect models and imperfect mapping algorithms. Scientists and technologists who produce the information and those who use it cannot be certain about the true values of the soil properties and soil classes in a region, and they must acknowledge the fact. That uncertainty can best be characterized by probability distributions. Geostatistics, based on such distributions, has become fashionable in the last 30 years or so for quantifying uncertainty in spatial information, and rightly so as it quantifies the uncertainty in its predictions. Uncertainty in soil information also propagates through agronomic and environmental models. It must be communicated to end users because the validity of their decisions depends on it.

Key points

- All information about the soil embodies error.
- Acknowledgement of error translates into users being uncertain about the true values of soil properties and classes.
- Uncertainty can best be quantified by probability distributions.
- Geostatistics provides the technology to quantify uncertainty in spatial soil information.
- The propagation of uncertainty in soil information through agronomic and environmental models can be traced with Monte Carlo simulation.
- Communication of uncertainty to end users and how uncertainty can be incorporated in decision making needs more attention than it has received.

Introduction

Uncertainty is present in our daily lives. It affects our decisions on what to do. The weather forecast might tell us that there is a 60% chance that it will rain: we take umbrellas. If it says that the chance of rain is only 10% we might decide to leave our umbrellas at home and risk getting wet. More seriously, farmers want to know the likelihood of disease in their crops and the deficiencies in plant nutrients in the soil. These are matters that affect profit and loss of farm business. Agencies responsible for public health and environmental protection need to weigh the risk of doing nothing in the face of uncertain threats against the cost of acting unnecessarily to counter them when the threats are almost non-existent. There are many examples of decision making problems

involving uncertain soil information. They include the remediation of polluted soil, the prevention of soil erosion, and the mitigation of pesticide leaching. They are practical matters, not purely academic exercises in statistics.

All measurements of soil properties (and other environmental variables) contain error in the sense that they depart from the true values. That error arises from imperfections in the analytical instruments, from the people who use them and from errors that occur during the processing of the recorded data to make them suitable for storage in information databases. Short-range spatial variation is another source of error, given that soil samples are never returned to where they were taken and sampling locations have positional error. Soil taken from location s and analyzed in the laboratory might differ substantially from the soil at location $s + h$, even if $|h|$ is as small as a few decimeters. Composite soil sampling can diminish these differences, but some error inevitably persists because even such a composite is still only a sample of all the soil at that site. All this means that we can never be sure about the true state of the soil: we, the producers and users of soil information, are to some extent uncertain.

Uncertainty tends to increase when measurements of basic soil properties are used to obtain derived ones via pedotransfer functions or mechanistic models of dynamic soil processes, for example. Interpolation from measurements to create maps of soil properties adds to the errors of measurement and so too increases uncertainties. We must conclude that considerable uncertainty is often associated with the information that is stored in soil databases and presented in various forms, including maps. This does not mean that the information is of no value; uncertainty is not the same as ignorance. In many cases we do know a great deal about the soil, but we must also acknowledge that the information is not perfect.

Some numerical expression of the uncertainty is important because it is needed to determine whether the information is sufficiently accurate for the purpose that a user has in mind. Soil data of too poor a quality might lead to flawed decisions with serious undesirable consequences, both economic and environmental. For instance, the European legislation on the use of pesticides in agriculture depends crucially on the leaching potential of these substances to the ground- and surface-water, which in turn depends importantly on soil properties. In these circumstances users should be aware of the quality of the soil information so that they can be sure that it is sufficiently reliable for their purposes. Ideally they should account for the uncertainty of the information when making their decisions.

This chapter (i) provides a statistical definition of uncertainty in soil information; (ii) extends this definition to uncertainty in spatial soil information; (iii) reviews methods that are used to quantify uncertainty in soil information, while paying attention to different sources of uncertainty; (iv) shows how uncertainty in soil information propagates through subsequent analyses; and (v) explains how uncertainty information can be used in decision making. It focuses on the quantification of uncertainty of soil properties that are measured and recorded on continuous scales: properties such as pH, particle-size distribution, and soil organic matter content. The chapter also addresses uncertainty of categorical variables, such as soil type and diagnostic properties recorded as present or absent, i.e. binary variables. It begins with defining uncertainty in a single soil measurement.

Defining and quantifying error and uncertainty in soil data

Single soil measurements

The concept of error and uncertainty is perhaps best introduced with an example. Consider a soil sample that is analyzed for clay content in the laboratory. Suppose the outcome of the analysis is 38.4%. Because of imperfections in technique, equipment or operating conditions, however, the measurement is subject to error, and the true value almost certainly differs more or less from the measured value. Perhaps it is 36.1%, or perhaps 40.0%: we cannot ascribe a single value to the true clay content. We are in effect uncertain about the true value. But we are not completely ignorant: we have a good idea of the clay content. Given the measurement of 38.4% we should consider it highly unlikely that the true clay content is greater than 60% or smaller than 20%. With this in mind we should be able to list a collection of possible values of the true clay content, and to associate a probability with each of them. In other words, we should be able to characterize the true clay content or the measurement error of it with a probability distribution.

For a continuous variable such as clay content one can usually characterize the measurement error by a normal (Gaussian) distribution (Fig. 1). It is a remarkable fact that measurement errors in many fields of endeavor have this distribution, first recognized by Gauss early in the 19th century, though the distribution itself had been formulated earlier by de Moivre and Laplace. It seems to arise because measurement error comprises numerous apparently independent random effects, which when summed give rise to the normal distribution, a result known as the Central Limit Theorem. In the measurement of clay content, for example, many disturbances contribute to the error: drying, grinding, sieving, pipetting or laser diffraction, instrumental fluctuation and so on. Together these lead to an approximate normal distribution, which one can verify by plotting histograms or plotting quantiles of the observed values against those of a normal distribution (Q–Q plots), based on repeated measurements of the clay content of the same soil sample, such as is done in proficiency testing. There are also many variables for which the measurement errors are better represented by lognormal distributions; for these it seems that individual sources of error are multiplied rather than summed. Again, one can see this by plotting histograms and Q–Q plots of repeated measurements.

Statistical model of measurement error

Representing an uncertain soil property by a probability distribution effectively defines a statistical model. This model states

$$Z_T = z_M + \varepsilon, \quad (1)$$

Fig. 1 Probability density of the normal distribution representing measurement or prediction error. Top: univariate case, with μ the mean (systematic error) and σ the standard deviation (measure of random error). Lower and upper limits of a 95% confidence or prediction interval are also indicated. Bottom: contour lines of a bivariate probability distribution of errors at locations $\mathbf{s}$ and $\mathbf{s}'$. Marginal densities projected on the axes. Note that the rotated ellipses indicate a positive correlation between the errors at the two locations.

where Z_T is the true soil property value, z_M a measurement of it, and ε the measurement error. Note that Z_T is written in upper case (capital letter) and z_M in lower case. This is to distinguish the stochastic Z_T (a random variable with a probability distribution) from the deterministic quantity z_M (the measured value). The measurement error ε is also stochastic, and here assumed normally distributed. Its probability density p is given by

$$p(e) = \frac{1}{\sigma\sqrt{2\pi}} \exp \left\{ -\frac{(e - \mu)^2}{2\sigma^2} \right\}. \quad (2)$$

The normal distribution is fully characterized by two parameters: its mean μ , which in this case signifies the systematic measurement error, and its standard deviation σ , which signifies random measurement error (Fig. 1). The square of the standard deviation, i.e. σ^2 , is the variance.

A well managed laboratory aims to avoid bias, and instruments are calibrated and laboratory staff trained to achieve that. A consequence is that the mean of ε may be assumed to be zero, and its standard deviation may be estimated from replicated measurements on the same soil sample. If the same soil sample is analyzed by several laboratories then ε may be decomposed into multiple components, such as the batch, laboratory and residual error. For instance, using data from the Wageningen Evaluating Programmes for Analytical Laboratories (WEPAL, 2022), Van Leeuwen et al. (2021) estimated the standard deviation of the measurement error of total organic carbon as 0.64%, with between-laboratory variation contributing more than variation within laboratories.

We do not know what the true value in Eq. (1) is. All we can say is that it is one of an infinite number of values represented by a probability distribution; we treat it as a random variable and denote it as Z_T . It is not that we believe that the world is stochastic

(Webster, 2000). In other words, we propose a statistical model of a reality that in itself is deterministic, and this model provides us with an estimate of our uncertainty about the true value. A narrow distribution (i.e. small standard deviation) conveys the notion that we are fairly certain about the true value, whereas a wide distribution (large standard deviation) means that our uncertainty is large. In the pathological case of an infinitely wide distribution (i.e. one that has infinite variance), we should be ignorant.

Estimating the measurement error standard deviation from replicates

A complete description of a measurement error requires specification of its probability distribution, but if it is assumed that the error is normally distributed about zero, i.e. has no systematic error, then all that is needed to characterize the error is its standard deviation σ . As mentioned above, σ can be estimated from replicated measurements. Fig. 2 shows a histogram of 58 measurements of total organic carbon (TOC) of the same soil sample (WEPAL, 2022). The mean is 35.58 g kg^{-1} and the standard deviation is 6.60 g kg^{-1} . Thus, if we assume that this standard deviation is representative of the random laboratory error of measuring TOC, and if for another soil sample we had only one measurement, say 50.92 g kg^{-1} , then our estimate of the TOC of that soil sample would be its measured value, with an uncertainty expressed by a standard deviation of 6.60 g kg^{-1} . If we further assume that the measurement error is normally distributed then we can state with 95% confidence that the true TOC value is in between $50.92 - 1.96 \times 6.60 = 37.98 \text{ g kg}^{-1}$ and $50.92 + 1.96 \times 6.60 = 63.86 \text{ g kg}^{-1}$. Here, the value 1.96 is taken from the standard normal distribution, and we assume that the standard deviation of the measurement error is constant. In practice we often find that it is proportional to the measured value, meaning that σ is larger in case of a larger measured value. A decision between constant and proportional errors may be based on repeated measurements of multiple soil samples and plots of the standard deviation for each sample against its average measured value.

We can diminish uncertainty about the true TOC value of the soil sample by taking the average of replicated measurements. For instance, in this specific case where we had 58 independent measurements of the same soil sample, we are 95% confident that the true TOC lies between $35.58 - 1.96 \times 6.60/\sqrt{58} = 28.88 \text{ g kg}^{-1}$ and $35.58 + 1.96 \times 6.60/\sqrt{58} = 42.27 \text{ g kg}^{-1}$. This is because from sampling theory we know that the average of n independent measurements has standard deviation $\sigma/\sqrt{n}$; this is the standard error of the mean. So, to double accuracy (effectively to halve the uncertainty) we need to quadruple the number of measurements. In the example above with a standard deviation of 6.60 g kg^{-1} , the standard error would be 2.09, 1.04 and 0.52 g kg^{-1} for samples of size 10, 40 and 160, respectively. This 'square root law' relation between the standard deviation and standard error might seem somewhat daunting to investigators when they plan sampling and measurement campaigns, but that is how it is.

Proximal soil sensing and model errors

In recent years the use of proximal soil sensing (Viscarra Rossel et al., 2010) has grown rapidly because it is much cheaper to measure soil properties this way than by wet chemistry. However, the techniques come at a price: these measurements tend to be more uncertain. This is because the statistical methods used to convert spectral signals to values of soil properties introduce additional uncertainty. Perhaps the most often used conversion method is partial least squares regression. The residual variances of this method should be added to the variances of the wet chemistry measurements to quantify the uncertainty of the proximal soil sensing estimates (Takoutsing et al., 2022). This additional error might be small for some soil properties and sensors, but it can be

Fig. 2 Histogram of 58 replicated measurements of total soil organic carbon (g kg^{-1}) of the same soil sample. Source: WEPAL (2022). International Soil-Analytical Exchange Programme. <https://www.wepal.nl/en/wepal/Home/Proficiency-tests/Soil/Proficiency-tests/ISE.htm>.

much bigger for others. This additional uncertainty may be termed ‘model uncertainty’, though it results from both an imperfect model connecting the signals from the sensors to the soil and imperfections in the sensors themselves. Next to measurement uncertainty, model uncertainty is an important source of uncertainty in soil data. It also occurs when properties that are hard or time-consuming to measure are predicted from properties that are straightforward and relatively cheap to measure with pedo-transfer functions (Stenemo and Jarvis, 2007; Deng et al., 2009) or when soil quality indicators are derived from basic soil properties and classes (Nosrati, 2013). Mechanistic soil process models also have model uncertainty. One might quantify model uncertainty in particular circumstances, but this might lack generality. For instance, one would expect a model of soil erosion constructed for the USA and calibrated with data from the USA to serve well in the USA. But it might perform less well, even badly, in the different circumstances of, say, China.

It is beyond the scope of this chapter to provide a full treatment of model uncertainty. Interested readers are referred to Brown and Heuvelink (2005).

Spatial soil information

Farming technology has advanced apace in recent years. Machines can now be programed to vary the amounts of fertilizer in response to known or estimated local concentrations of nutrients, provided their locations are known. This is an important development in precision agriculture (Oliver, 2010). In the same vein, an environmental protection agency might want to remove soil polluted by a toxic metal if it knows where the soil’s load of that metal exceeds some statutory limit, or alternatively forbid cultivation or grazing there. In principle, both farmers and protection agencies want maps of soil conditions. Neither farmers nor protection agencies can measure the soil everywhere; they can at best sample on small supports, typically cores a few cm in diameter or small areas within which cores of soil are bulked. Yet they wish to know the concentrations everywhere, so that they can treat the soil in accord with those concentrations. They therefore turn to mapping, and for this they may use various approaches, as outlined in other chapters of the Encyclopedia. The focus of this and subsequent sections is on quantifying the uncertainties that are introduced by mapping. But before we address this we must first extend the statistical model of uncertainty of a single soil measurement to a model for uncertain spatially distributed soil properties.

Statistical model of errors in spatial soil variables

The extension of the statistical model presented in the previous sections to spatially distributed soil properties starts by our recognizing that Eq. (1) may be copied to all locations $\mathbf{s}$ in a region D :

$$Z_T(\mathbf{s}) = z_p(\mathbf{s}) + \varepsilon(\mathbf{s}) \quad \text{for all } \mathbf{s} \in D. \quad (3)$$

Here the measurement z_M in Eq. (1) has now been replaced by a soil prediction z_p to acknowledge that in this case we compare a predicted or mapped soil property to a true value. The mapped property is typically not directly measured but obtained by prediction, be it human (i.e. what was formerly convention) or statistical (i.e. digitally). This implies that spatial interpolation error will add to the uncertainty. Thus, ε is no longer solely a measurement error but rather a spatial prediction error and is likely to have a larger variance than the measurement error of Eq. (1).

Geostatistics and machine learning

Eq. (3) shows that quantification of the map error requires the specification of the probability density of the prediction error for all locations in the region. If we invoke the assumption of a normal distribution again then we shall need the mean $\mu(\mathbf{s})$ and standard deviation $\sigma(\mathbf{s})$ for all $\mathbf{s} \in D$. This might seem a formidable task, but it turns out to be a routine by-product of kriging, i.e. of mapping geostatistically. It is explained in some detail in the geostatistics chapter of the Encyclopedia and fully in text books (e.g. Webster and Oliver, 2007; Chilès and Delfiner, 2012). To krig a soil property one needs a geostatistical model, for which certain assumptions are made; these usually comprise second-order stationarity and isotropy. If the assumptions are satisfied then kriging produces unbiased predictions while minimizing $\sigma(\mathbf{s})$, the kriging standard deviation.

There are various forms of kriging that depend on the specific assumptions about the variables being predicted and mapped. They include lognormal kriging, which is used to predict variables that appear to have lognormal distributions. Indicator kriging was developed to predict and map variables that have distributions not readily parameterized; the procedure is somewhat cumbersome, and the prediction errors are no longer normally distributed (Webster and Oliver, 2007). These disadvantages are overcome by the technically more advanced disjunctive kriging. Ordinary and simple kriging are based on models in which there is no spatial trend. Trend, a fixed effect, can be accommodated in universal kriging, regression kriging and kriging with external drift, where the latter two take into account fixed effects of environmental covariates (Hengl et al., 2004). Nevertheless, whichever kriging method is used the uncertainty of the predictions is quantified. Typically, the prediction errors are small in densely sampled regions and large in sparsely sampled ones and close to the borders of the regions being mapped. In other words, the sparser is the sampling the greater is the uncertainty. The magnitude of uncertainty also depends on the spatial correlation of the target variable, as quantified by the variogram. The geostatistics chapter provides details.

Fig. 3 Lower (A) and upper (B) limits of a 90% prediction interval of the SoilGrids 2.0 global map of pH_{water} (units in 10pH) in the 60–100 cm depth interval, as obtained using Quantile Regression Forests. Note that differences between the two maps are small, indicating high map accuracy. From Poggio L, de Sousa LM, Batjes NH, Heuvelink GBM, Kempen B, Ribeiro E, and Rossiter D (2021) SoilGrids 2.0: Producing soil information for the globe with quantified spatial uncertainty. *Soil 7*: 217–240.

If soil maps are derived by machine learning instead of geostatistics then it is more difficult to quantify the prediction error at each location in a region. The most common approach for this in digital soil mapping is Quantile Regression Forests (Meinshausen, 2006; Vaysse and Lagacherie, 2017; Poggio et al., 2021). This method requires no assumption of a normal distribution; instead it computes the quantiles of the probability distribution in a non-parametric way. All quantiles together characterize the probability distribution of the prediction error. GlobalSoilMap standards (Arrouays et al., 2014) request the 0.05 and 0.95 quantiles, which are the lower and upper limits of a 90% prediction interval, respectively. Fig. 3 shows an example.

Multivariate distribution of soil map errors

A comprehensive definition of soil map uncertainty also requires that the multivariate or joint distribution of map errors at multiple locations is specified. The bivariate probability distribution specifies the joint distribution of map errors for pairs of locations s and s' in D . An example of this bivariate distribution is given in the bottom panel of Fig. 1, where it is portrayed by 'contour' lines of equal probability density. Map errors are often positively correlated if the distance between s and s' is small, as is illustrated by the

rotated ellipses in Fig. 1. Fig. 1 also shows that the marginal, univariate distributions of the errors at the two locations are obtained by projection of the bivariate distribution on the two axes.

If we invoke the multivariate normal distribution and assume that the map errors at all locations in the region are jointly normally distributed then all that is needed to characterize this distribution is a vector of means and a variance–covariance matrix. These so-called two-point statistics are enough because for the multivariate normal distribution the higher-order moments are completely determined by them.

Kriging implicitly quantifies the correlation between map errors at any pair of locations; that is, it quantifies the correlation between the kriging prediction errors $\varepsilon(s)$ and $\varepsilon(s')$. They are usually not explicitly computed, but are taken into account when values from the joint distribution are obtained by conditional spatial stochastic simulation (Webster and Oliver, 2007, Chapter 12). Fig. 4 shows an example. These simulations or ‘possible realities’ are created with the help of a pseudo-random number generator. In principle, an infinite number of possible realities can be generated. Each of these could be the ‘true’ reality, but we do not know which one it is; we are uncertain. Thus, the differences among them express our uncertainty about the true situation at any location. In fact, the spread (represented by the standard deviation) computed from very many possible realities will equal the kriging standard deviation. Their average equals the kriging prediction, which implies that maps of the prediction errors (i.e. the differences between the true values and the kriged predictions, see bottom row of Fig. 4) average to zero over many simulations. This is a consequence of kriging’s unbiasedness. Spatial stochastic simulation and the possible realities that it produces are essential inputs for the propagation of uncertainty through Monte Carlo methods, as described below.

Machine learning methods cannot compute the joint distribution of map errors at multiple locations because they are essentially non-spatial and do not account for residual spatial correlation (Heuvelink and Webster, 2022). If one requires maps of prediction errors that take into account spatial correlation, for computing spatial averages and their uncertainty, for example, then a possible solution is to krig the residuals of the machine learning model (e.g. Szatmári et al., 2021).

Cross-correlation, positional uncertainty and uncertainty of categorical soil variables

Environmental scientists and agencies often want to consider several soil properties together and the errors arising from their analysis. If two properties are cross-correlated then one can use a similar approach to that above to characterize the joint distribution of $\varepsilon_1(s)$ and $\varepsilon_2(s)$, or that of $\varepsilon_1(s)$ and $\varepsilon_2(s')$ (Heuvelink et al., 2007). For example, cadmium and lead often occur together as pollutants and are correlated in the ordinary Pearson sense. If they are kriged to map the pollution their kriging prediction errors are likely to be positively correlated also, if only because a hot spot of high pollution may have been missed in sampling. Moreover, the interpolation error of cadmium at location s will probably be positively correlated with that of lead at location s' , if the distance between s and s' is smaller than the variogram’s range. All these correlations can be quantified using cokriging (Webster and Oliver, 2007, Chapter 10).

If measurement error is the only source of uncertainty then the correlation between errors of different soil properties may safely be assumed zero. For instance, even though organic carbon and total nitrogen in soil are usually positively correlated, their measurement errors are likely to be uncorrelated. This is because the two properties are measured in different ways and the measurement errors do not influence each other. Compositional data, such as particle-size distributions, are an exception. The proportions of sand, silt and clay measurements will be constrained to sum to 1 or to 100%. Their measurement errors are likely to be negatively correlated, therefore, because a positive measurement error for one proportion must be compensated by a negative measurement error for another.

Positional uncertainty

So far we have considered uncertainty only in the measured or predicted values of soil properties. In geographical information science this is known as ‘attribute uncertainty’. It is different from ‘positional uncertainty’, which refers to uncertainty about the geographic position of spatial objects, such as sampling locations. Positional uncertainty of soil data can be substantial, particularly with legacy data arising from sampling campaigns of many years ago. One can define positional uncertainty in a similar way to attribute uncertainty using a bivariate probability density, representing uncertainty in latitude and longitude. Positional uncertainty can be translated into attribute uncertainty if short-range spatial variation is known. When a perfect measurement at location s is taken to represent a soil property at $s + h$, with h a possible positional error, then this short-range variation means that the property at s almost certainly differs from that at $s + h$. Therefore, even though the measurement at $s + h$ is free of error, it nevertheless represents the property’s value at s with error.

Errors and uncertainty in soil class maps

For many years spatial variation in soil was represented solely by maps of soil classes, and those classes were defined by the soil in a profile regardless of any lateral variation. Errors were recognized, either because the boundaries between classes were drawn in the wrong places or because the parcels delineated contained profiles that did not belong to classes depicted, or usually both. In other words, pedologists and the clients for whom they mapped the soil were aware of the uncertainty of these maps, although it was rarely quantified.

Fig. 4 Allier study area in France. Top left: stars show sampling sites of moisture content at field capacity and porosity; circled sites are those where in addition moisture content at wilting point was measured. Top right: kriging map of topsoil porosity. Middle row: two realizations of topsoil porosity, obtained using conditional spatial stochastic simulation. Bottom row: error maps corresponding with the two realizations, obtained by subtracting the kriging map from the realization. See Heuvelink (2018) for details.

Uncertainty in categorical soil variables such as soil type obviously cannot be characterized by models such as Eq. (1) and Eq. (3) nor can they be normally distributed. But we can form a discrete probability distribution by listing all possible values of a variable of interest at each location s and their associated probabilities. Clearly, these probabilities must all be non-negative and add to 1. While the definition is easy, acquiring them in practical situations for all locations in a region is more difficult. Indicator geostatistics may be used (Webster and Oliver, 2007, Chapter 11), or perhaps more advanced statistical methods such as the generalized linear geostatistical model (Diggle and Ribeiro, 2007; Kempen et al., 2012). Quantifying spatial dependence of uncertain categorical soil

variables is especially difficult. Bivariate distributions are not enough, and so-called ‘multi-point’ statistics are required, using techniques such as multi-point geostatistics (Meerschman et al., 2013).

As a last resort one may rely on expert judgment to quantify the uncertainty of categorical soil variables (O’Hagan, 2012; Lark et al., 2015). For example, to assess uncertainty of a soil class in a pit, several experts might be asked to classify the soil independently. If they all agree then the uncertainty will be small or absent, but if they do not then the distribution of the designated classes may be used to represent the uncertainty (Van Leeuwen et al., 2018). In fact, one can also use the judgment of experts for assessing uncertainty of properties measured and recorded on continuous scales, particularly when there are no replicates of field and laboratory measurements and when soil maps are made by non-statistical methods (Truong and Heuvelink, 2013).

The uncertainty of a map of soil classes as a whole can also be represented in a confusion matrix. If there are m classes then the confusion matrix, C , will have m rows, one for each of the mapped classes, and m columns, again one for each class. Each cell $C[i, j]$ of the confusion matrix contains the number of instances that the soil class at a location in the region that is mapped as class j is in fact class i . In practice, the confusion matrix is estimated from independent validation data, which are preferably placed randomly within the mapped region. The counts for each combination of map class and true class are then entered into the matrix. Counts in the diagonal of the matrix represent agreement; those in off-diagonal elements disagreement or error. The purity of the soil map may be expressed as the proportion of instances that the map was correct:

$$\text{purity} = \frac{1}{n} \sum_{i=1}^m C[i, i], \quad (4)$$

where n is the total number of observations. Note that the confusion matrix provides only a summary measure of the map accuracy. It is not spatially explicit. In contrast, indicator kriging and the generalized linear geostatistical model specify the map uncertainty for each and every location separately.

Change of support

Many users of soil maps are not interested in predictions of soil properties at points; they are much more concerned with averages of soil properties over larger areas of land. Such averages can be predicted by block kriging, as explained in the geostatistics chapter of the Encyclopedia. The blocks might be rectangular, even square, but they may take irregular shapes. They may even be as large as the entire mapped region. The geostatistics chapter also explains that the block kriging standard deviation is typically much smaller than the point kriging standard deviation, especially when the short-range variation is large. The reason for this is that within-block variation averages out when block means are predicted, and hence predicted block averages are more accurate than point predictions. So, the uncertainty of soil maps depends strongly on the support, where ‘support’ is defined as the area or volume over which a measurement or prediction is made. If the mapping did not include a change of support then the prediction support will be the same as the measurement support, which is usually treated as point support and can actually be either that of a single soil sample or a composite of several spread over some small area. Since uncertainty depends on the support, any database that reports the uncertainty of its soil maps must record the support of the map predictions as metadata.

In some circumstances users require predictions on smaller supports than those of the measurements, and if they do they may resort to area-to-point kriging (Kerry et al., 2012). This is rare for soil properties that are observed directly because the measurements are made on small supports. When properties are recorded or estimated by remote sensing, however, the supports can be substantially larger than users’ requirements; so too can those associated with the polygons of legacy soil maps (Kerry et al., 2012). Another example is the use of area-to-area kriging in the vertical dimension, to predict soil properties for layers that differ from those from which the soil sample was taken (Orton et al., 2016). In contrast to block kriging, area-to-point kriging leads to larger standard deviations because it makes predictions over smaller supports than those of the measurements.

Spatial support and resolution

Spatial support is often thought to be the same as spatial resolution. That is unfortunate; they are not; they differ in principle. For instance, the pH maps shown in Fig. 3 have a spatial resolution of $250 \text{ m} \times 250 \text{ m}$, but because the methods used to create these maps did not incorporate a change of support, the support of these maps is the same as that of the training data, that is the point support of the soil samples. The prediction interval limits shown in Fig. 3 thus refer to predictions at point support. The prediction interval would probably be narrower (smaller standard deviation) if the pH were predicted over a $250 \text{ m} \times 250 \text{ m}$ support, but this can be done only if the variogram of the map error is known and a geostatistical approach is used. One possibility is to apply block kriging to the residuals of a machine learning model. Szatmári et al. (2021) took this approach to quantify uncertainty of the change of soil organic carbon in Hungary between 1992 and 2010. They showed that uncertainty on large supports was substantially smaller than on small supports. Because of this they could show that the concentration of organic carbon in the soil had changed significantly between 1992 and 2010 for counties and the entire country, whereas for square blocks of $1 \text{ km} \times 1 \text{ km}$ and $10 \text{ km} \times 10 \text{ km}$ most predicted changes were not statistically significant, and on the point supports they found none.

Uncertainty propagation

We mentioned above the use of pedotransfer functions to predict soil properties that are difficult or time-consuming to measure from simpler basic ones. These are examples where soil information is used to compute derived properties. Soil maps are frequently used in this way—to predict by modelling crop yield, the emission of greenhouse gases, water infiltration, pesticide leaching and erosion, for example. Maps of basic soil properties are also used to derive more complex soil properties, such as soil functions and soil threats. The outputs of these models and analyses suffer from two main sources of uncertainty. One is model uncertainty, which may be split in uncertainty concerning the form of the model and uncertainty of the actual parameters of the model (e.g. Chapagain et al., 2022). Here we focus on the second one, namely uncertainty of the input variables. If the input to a model is uncertain then that uncertainty propagates into the model's output.

There are two main methods for analyzing the propagation of uncertainty through environmental models. The Taylor series method can be used for fairly simple models that are described by a continuous-differentiable mathematical function. It approximates these models locally by a linear or quadratic function, after which the propagation of uncertainty can be computed analytically (Heuvelink, 2018). The Monte Carlo method is more flexible, but it is also computationally demanding. It requires the joint probability distribution of all uncertain inputs, from which realizations or 'possible realities' are generated with a pseudo-random number generator. For spatially distributed inputs one makes use of spatial stochastic simulation, as discussed above. By repeatedly sampling from the input distribution and running the model for each realization, one obtains an equivalently sized sample from the model's output distribution. Thus, Monte Carlo simulation involves the following steps.

1. Repeat N times (typically $100 \leq N \leq 10,000$):
 - (a) Generate a realization of each uncertain model input.
 - (b) Run the model with this set of realizations and store the model output.
2. Compute parameters of the distribution of the N outputs and use these to characterize the uncertainty of the model output (e.g. mean, standard deviation, percentiles).

The Monte Carlo method is flexible in that it imposes no restrictions on the model. It can also deal with categorical uncertain inputs, whereas the Taylor series method cannot. The main difficulties are the computational burden and the need to characterize input uncertainty with a probability distribution, which can be a complex task for spatial inputs, as mentioned above. The Monte Carlo method involves an approximation error, but one can diminish this error by increasing the number, N , of Monte Carlo runs.

There are numerous applications of Monte Carlo uncertainty propagation in soil science. Some examples are Bishop et al. (2006), Van den Berg et al. (2012), and Benke et al. (2018). One can use it also to assess the contribution of individual uncertain inputs to the overall output uncertainty. One repeats the uncertainty propagation analysis with all uncertainty sources present except that for which the uncertainty contribution is required. This input is deemed certain and set to a representative value (usually the mean of the probability distribution). One then assesses the contribution of this input to the model's output uncertainty by evaluating the reduction of uncertainty that is caused by setting it to its representative value.

Uncertainty propagation example

Fig. 5 shows an example where model uncertainty and input uncertainty were propagated by the Taylor series method. The example refers to the Allier region in France shown in Fig. 4. A simple pedotransfer model that took the shape of a multiple linear regression model and that predicts the soil moisture content at wilting point from soil moisture at field capacity and soil porosity was first calibrated with data from 12 locations in the region. Model uncertainty was quantified by the variances and covariances of the regression coefficients and the residual variance; input uncertainty was derived by cokriging. Fig. 5 shows that the standard deviation of the model's output (i.e. of the soil moisture at wilting point) is smaller than that of the predicted output, although there are locations where the ratio of the two exceeds 0.5. This occurs mainly at places far from where the model inputs were measured (see top left panel in Fig. 4). The bottom panel of Fig. 5 shows that in this case the contribution of input uncertainty was much larger than that of model uncertainty. This indicates that one could obtain a more accurate map of soil moisture content at wilting point by taking more measurements of soil moisture at field capacity and soil porosity. It is remarkable that model uncertainty had a small contribution, given that the model was calibrated on only 12 paired observations.

The added value of uncertainty information

We explain above how uncertainty in soil measurements and soil maps can be quantified and used in analyses to propagate uncertainty. The quantification and propagation of uncertainty makes substantial demands for data and is not easily done. So, is it worth the effort? What is the added value of an uncertainty assessment of spatial soil information? Below we list several purposes that it serves.

1. First and foremost, any self-respecting investigator should want to check the quality of his or her results before they are made public. We should not publish soil data that have large errors nor publish poor soil maps. If they are the only data available, however, we should be honest about that and report their accuracy.

Fig. 5 Uncertainty propagation in the Allier study area. Top left: predicted soil moisture content at wilting point derived from kriged maps of soil moisture at field capacity and soil porosity using a pedotransfer function. Top right: standard deviation of soil moisture at wilting point, obtained using a Taylor series uncertainty propagation analysis where both model uncertainty and input uncertainty were included. Bottom left: Contribution (%) of model uncertainty to overall uncertainty in soil moisture content at wilting point. Bottom right: Contribution (%) of input uncertainty to overall uncertainty in soil moisture content at wilting point. See Heuvelink (2018) for details.

2. Clients and end users must know the quality of soil information so as to judge whether the information is good enough for their intended use of it. For example, there is serious regard for the soil's ability to store more carbon and mitigate climate change (Amelung et al., 2020). There have been claims of success in sequestering carbon, but these claims must be verified. One can do that by estimating the increase in organic carbon in a region between the start and end date of a project, though one would want to test the increase for statistical significance to be confident that the increase was real. And that would necessitate the quantification of the uncertainty.
3. Quantified uncertainty also helps producers of spatial soil information because it allows them to compare the performances of two or more mapping techniques, to determine which performs best, and to decide which technique to use in any particular case. For example, do many cheap, but inaccurate, observations from proximal sensors provide more accurate maps than few expensive measurements by wet chemistry? Does it pay to replace a simple empirical erosion model by a complex mechanistic model that needs many more input and calibration data but could predict erosion rates more accurately? These questions can be answered only if the uncertainty is quantified.
4. Geostatistical modelling of uncertainty enables one to see how uncertainty is influenced by a change of support. The larger are the supports at which one predicts the greater is the certainty. But that in itself is not a sufficient reason to predict on large supports. The prediction must depend on the application at hand; what size of support does the user need or demand? The farmer, for example, who wishes to apply fertilizer at a variable rate would want predictions of nutrient concentrations on a support that matched the width of his fertilizer spreader. He or she would be unlikely to want predictions on point supports from which the measurements were made. In like manner, emissions of nitrous oxide from agricultural land might be estimated for fields, farms, large regions, even whole countries, if the aim is to learn how much each is contributing to the total nitrous

oxide in the atmosphere. There is a trade-off between accuracy and spatial support, and knowing this relation is indispensable for informed decisions on the spatial scale at which to work and present results.

5. Uncertainty in soil data propagates through models and spatial analyses to output predictions and maps. Quantifying and tracking that uncertainty is valuable because it enables end-users to know how accurate the results are, and that in turn enables them to take into account that uncertainty when making decisions. They can do so, however, only if the uncertainty in the input, i.e. in the data, is quantified. Uncertainty propagation analysis can tell how much each of the uncertainty sources contributes to the output uncertainty. This helps modelers and users to take rational decisions on how to reduce uncertainty about the model output. It is usually best to tackle the main source of uncertainty (i.e., the weakest link in the chain), although this also depends on how easy or difficult it is to reduce input uncertainty. For instance, if an interpolated map of the rootable depth is the main source of uncertainty of an agronomic model that predicts potential yield in West Africa, it may not be easy to collect more point data on rootable depth in the region to improve the map.
6. Quantified uncertainty can be included in decision making, as in risk analysis. Many users want to avoid risk; they would like certainty. They cannot have it, of course, but they can be told what the uncertainty is, and that should help them when they are deciding what to do with the information provided. For instance, a farmer might be unwilling to buy fertilizers if plague, pests or drought are likely seriously to cause loss of his crop even if the expected net-return of fertilization is positive. Breure et al. (2022) showed how farmers can account for uncertainty in spatial decision making. Incorporating uncertainty information in spatial decision making has not yet received the attention it deserves by soil scientists, though as Lark et al. (2022) remarks there is much potential benefit for it.

Finally, note that for some purposes soil maps can be validated and their uncertainty quantified by design-based, probability sampling and statistical analysis and inference (Brus et al., 2011). It has several important and attractive properties. It requires no assumptions about the nature of the spatial distribution, is easily applied, and is backed by well-founded theory. It has its disadvantages, too. It can provide only summary measures of a map's accuracy; it cannot easily estimate the prediction errors for supports larger than those of the data; and it requires an independent probability sample from the population (i.e., the study area). It is a large subject well beyond the scope of this chapter, but it is comprehensively covered by De Gruijter et al. (2006).

Conclusion

Soil information is rarely if ever free of error. The main sources of uncertainty are measurement error, classification error, interpolation error and model error. That uncertainty in soil information can be adequately characterized by probability distributions, although such distributions might be complex and difficult to assess when spatial variation and cross-correlation between soil properties are involved. There are considerable advantages in quantifying uncertainty in soil information: it tells users whether the data are sufficiently accurate for their intended use, it helps producers of soil information to select the best mapping method, it allows analyses of how uncertainty in soil data propagates through environmental models, and it supports decision making under uncertainty.

Many soil databases provide no or only rudimentary information about the accuracy of the data they contain. This is certainly so for laboratory and field measurements, because laboratory errors are often not quantified or not copied into soil databases. Digital soil mappers take pride in routinely quantifying the prediction uncertainty of their maps, but not all of this information is transferred to soil spatial databases. There is also much to be done to communicate uncertainty information better to end-users and help them to use this information in decision making.

Soil science is continuously advancing. New theories and models are proposed and tested, and new techniques for acquiring data help us to improve the accuracy of soil information. The information will never be perfect, however; uncertainty is here to stay. Nevertheless, we have the tools to control and express uncertainty, and soil scientists and practitioners are urged to learn to use them to everyone's advantage.

Abstract

Digital soil mapping (DSM) entails the creation and population of spatial soil information systems by numerical models inferring the spatial and temporal variations of soil types and soil properties from soil observation and knowledge derived from related environmental variables. This chapter summarizes the state of the science of DSM and the mechanics of its various implementations. It has moved from research to practical application and is now widely used as a method for making soil maps. The outlook for continuing research into DSM and related efforts is positive, because objective spatio-temporal assessments of the soil resources are needed and continually require updating.

Key points

- This chapter describes some of the underpinning mechanics of digital soil mapping, celebrates some of its successes, and identifies areas of the science which need further thought and work.
- Digital soil mapping has been borne out and developed alongside technological developments which include advances in computers and computer sciences, together with unparalleled growth in associated modelling technologies and widespread availability of digital Earth observation data.
- Digital soil mapping augments rather than replaces conventional soil survey and is recognized as an additive technology that enables delivery of richer spatial soil information and has the potential to deliver products customized to the needs of end-users.

Introduction

In recent times, we have witnessed the advancement of the computer and information technology ages. With such advances, vast amounts of data and tools in all fields of endeavor have become available. This has motivated numerous initiatives around the world to build spatial data infrastructures aiming to facilitate the collection, maintenance, dissemination and use of spatial information.

The science of digital soil mapping has been borne out of and developed alongside these technological developments. Digital soil mapping (DSM) is a numerical and model-based framework for inferring the spatial and temporal variation of soil types and properties from soil observation and knowledge derived from related environmental variables. Digital soil mapping has never been considered a replacement to traditional forms of soil survey and mapping, rather as a complementary tool, albeit quantitative in principle, to characterize the spatial and temporal properties of soils in ways that legacy soil mapping could not achieve.

There are many aspects to DSM, including its generalizations given different forms of soil information, diverse modelling frameworks and accommodation for both 2- and 3-dimensional vertical support, and the quantification of uncertainties, all of which are discussed in this chapter.

Digital soil mapping has matured as a science and is used as an operational tool throughout the world for the assessment and characterization of soils within both government and privately funded organizations.

Globally, the need for comprehensive and specific digital soil information has increased, particularly amidst emerging existential crises of climate change, land degradation, and unsustainable land management practices in an increasingly populous world. Digital soil mapping will continue to evolve together with the broader technological advancements. More importantly, it will also branch out further into digital soil assessment, for example in the quantification of soil function and ecosystem services. It is this derived information that is required for assessing the status of ecosystems more generally, rather than just the creation of digital maps of soil characteristics and properties. To date, we are already down that path, and well positioned to confront these environmental challenges given the large and active network of practitioners throughout the world.

Digital soil mapping concepts

The various threads in research on soil spatial prediction began to converge in the early 2000s. The development of fuzzy logic and geostatistics and then soil–landscape quantification in the 1990s, brought about a strong theoretical foundation that enabled modern digital soil mapping to emerge rapidly at the turn of the millennium. Two seminal papers were published in 2003 that summarized historical developments, albeit from different perspectives. Scull et al. (2003) wrote about past research in soil spatial prediction from a physical geography perspective and coined the term predictive soil mapping to describe the general approach. About the same time, McBratney et al. (2003) generalized the diversity of quantitative mapping approaches into a framework they called ‘scorpan.’ This uses a Jenny (1941) clorpt-like framework not for mere explanation but rather empirical quantitative description of soil–landscape relationships for spatial prediction. They called these activities digital soil mapping (DSM).

The ‘scorpan’ framework is more formally known as scorpan-SSPFe, which includes soil spatial prediction functions (SSPF) and autocorrelated errors (McBratney et al., 2003). The scorpan factors are:

- s: soil, its classes, or properties.
- c: climate, including precipitation and temperature.
- o: organisms, including vegetation, fauna, and other factors of the biotic environment.
- r: relief, or topography.
- p: parent material, including lithology.
- a: age.
- n: space, or spatial position.

The model is written as:

$$S_c = f(s, c, o, r, p, a, n) \text{ or } S_p = f(s, c, o, r, p, a, n)$$

where S_c is soil classes and S_p is soil properties or attributes. Considering soils are sampled at spatial coordinates x, y at an approximate point in time, $\sim t$, the model can be expressed explicitly as:

$$S[x, y, \sim t] = f(s[x, y, \sim t], c[x, y, \sim t], o[x, y, \sim t], r[x, y, \sim t], p[x, y, \sim t], a[x, y, \sim t], n[x, y, \sim t]).$$

Soil (s) is included as a factor because soil can be predicted from its properties, and soil properties from its class or other properties (McBratney et al., 2003). This additional soil information could be gathered from a prior soil map or from either remote or proximal soil sensing or even expert knowledge. The factor n means that soil can be predicted as a function of spatial position alone, as in the case of kriging, but it may also be predicted as a function of the distance from some landscape features such as streams, hilltops, roads or point sources of pollution, etc. Information that may represent the other scorpan factors is described in Table 1.

Table 1 Possible sources of information to represent the scorpan factors.

Scorpan factor	Possible representatives
s	Legacy soil maps, point observations, expert knowledge
c	Temperature and precipitation records, remote sensing derive climate data
o	Vegetation maps, species abundance maps, yield maps, land use maps, remote sensing derived vegetation indices
r	Digital elevation model, terrain attributes
p	Legacy geology maps, gamma radiometric information
a	Weathering indices, geology maps
n	Latitude and longitude or easting and northing, distance from landscape features, distance from roads, distance from point sources of pollution

Since the establishment of DSM in the early 2000s, there have also been developments and huge leaps forward in terms of Earth observation data from both remote and proximal sensing platforms. This has resulted in a proliferation of high-resolution environmental spatial data, and many of these can be used to represent various scorpan factors. Digital elevation models (DEMs) and satellite imagery data are two prominent examples. Subsequently, DSM techniques have been deployed to build or populate spatial soil information systems from relatively sparse datasets from the ground up. The DSM techniques have also been used to update or renew existing soil maps (e.g. [Kempen et al., 2009](#)). It is seen as a practicable framework for fulfilling the current and future demand for relevant soil information ([Searle et al., 2021](#)).

In practice, DSM starts by defining a mapping domain, and soil samples are taken based on an established sampling design. Several sampling designs for DSM have been developed, such as stratified sampling using *k*-means algorithm or conditioned Latin hypercube sampling. This is followed by intersecting the observations with a set of pedologically meaningful environmental layers. Then, fitting a mathematical or machine learning model to obtain a spatial soil prediction function. Once the model has been fitted at the observation points, it is then extended to all grid cell nodes of the raster layers giving a digital soil map. This three-component process is the hallmark of DSM ([Minasny and McBratney, 2016](#)), which entails:

1. The input which includes soil data and associated environmental covariates.
2. The modelling process, and
3. The output, i.e. the digital soil map with uncertainty.

This DSM approach is quite distinct from earlier notions of digital soil mapping that simply involved the digitization of conventional soil maps by electronic scanning. A more appropriate term for this would be digitized soil map.

Soil spatial prediction functions

The modelling step is crucial in the digital soil mapping process and fundamentally distinguishes it from digitized soil mapping. The form of the spatial soil prediction function $f()$ is usually determined at the outset. When deciding which mathematical model is the most appropriate for a given application, several factors are usually considered, including:

1. The operator's familiarity with the model.
2. The model's ease of application in the context of the project, the availability of covariates and the idiosyncrasies of the available soil information.
3. The model's complexity and its power to capture potentially complex soil–landscape relationships within the target mapping domain.

Many mathematical models are available to represent $f()$, and their development continues with advances in statistical and machine learning models. In general, some models, such as multiple linear regression or regression trees, are suited to modelling continuous variables whereas others, such as logistic regression or classification trees, are suited to modelling ordinal or nominal categorical data.

Some of the simplest models are simple linear models with either ordinary or generalized least-squares fitting. More complex models include generalized linear and additive models. Logistic regression models are a type of generalized linear model suited to modelling categorical variables. Recursive partition models such as classification and regression trees are particularly favorable because of their non-parametric structure and their capacity to deal with non-linear relationships between soil data and environmental covariates. For similar reasons machine learning algorithms (such as random forests and support vector machines to mention only two) and neural networks are often considered, as are deep convolutional neural networks, particularly in terms of incorporating spatial contextual information ([Padarian et al., 2019](#)) for which these algorithms are suited. Collectively, these model structures provide DSM practitioners with a rich and varied suite of options to explore complex soil spatial variation.

In terms of handling any spatial autocorrelation in the residual (e) that is likely to result from fitting a scorpan model, regression kriging (alternatively scorpan kriging; [McBratney et al., 2003](#)) or universal kriging could be used. Coupling a machine learning model with geostatistical modelling of the residuals is also a generalized regression kriging approach that is often used in digital soil mapping studies.

[Lark et al. \(2006\)](#) described a REML–EBLUP (residual maximum likelihood–empirical best linear unbiased predictor) model. The REML–EBLUP is intrinsically like regression-kriging in that both are mixed models where the observed data are modelled as the additive combination of fixed effects (the secondary environmental data), random effects (the spatially correlated residuals e), and independent random error. The difference is that REML estimates the parameters of the trend and covariance functions without bias. These parameters are then used in the EBLUP i.e. a general linear mixed model.

The application of formal geostatistical modelling approaches to categorical variables, such as soil classes, is relatively limited. [Kempen et al. \(2012\)](#) reminded us that the popular methods for categorical prediction of soil types to create a digital soil type map—multinomial logistic regression, classification trees etc.—are non-spatial models i.e. we do not consider spatial locational properties of the target variable as for continuous variables. Subsequently, they explored a generalized linear geostatistical model framework that addressed this issue. The method was theoretically appealing, but was computationally cumbersome and ultimately did not yield significant gains in accuracy when compared to a non-spatial multinomial logistic regression model.

Assessing digital soil map quality

In DSM, a model is created, and a map is produced, which then needs to be verified in terms of whether the resultant spatial patterns appear plausible across the landscape. To date this is a largely qualitative assessment, and usually requires expert elicitation or an assessment by the model creator who may be familiar with the area mapped and will be able to verify accordingly.

Quantitative assessments of map quality are usually done by assessing the fidelity between observations (observed data of soil phenomena) with corresponding co-located model predictions. For continuous variables, goodness of fit statistical measures are based on some form of deviation assessment such as bias and root mean square error between observations and predictions (Hastie et al., 2009). For categorical data, the measures include overall, user and producer accuracies together with indices such as the kappa coefficient.

For completely unbiased assessments of model quality, it is ideal to have an additional data set that is completely independent of the model data. When validating trained models with some sort of data sub-setting mechanism, keep in mind that the validation statistics will be biased. As Brus et al. (2011) explain, sampling from the target mapping area to be used for DSM is often from legacy soil survey. Consequently, these data are unlikely to have been collected using a probability sampling design. Therefore, the sample will be biased i.e. not a true representation of the total population. Thus, an independent probability sample is required. It is recommended that some random sampling from the target area be conducted, such as simple random sampling and stratified simple random sampling.

From an operational perspective it is usually difficult to arrange the additional costs of organizing and implementing some sort of probability sampling for determining unbiased model quality assessment. The alternative is to perform some sort of data sub-setting, such that with a data set split it into a set for model calibration and another set for validation. This type of procedure can take different forms: the two main ones being random-hold back and leave-one-out-cross-validation (LOCV). Random-hold back is where we may sample a data set by some pre-determined proportion (say 70%) which is used for model calibration. We then validate the model using the other 30% of the data. If the dataset is small, there could be a random chance that the model could overstate or falsely represent model confidence. To avoid such outcomes, this random split procedure needs to be performed many times, and the mean of such validation will provide a more representative assessment.

For k -fold validation we divide the dataset into equal sized partitions or folds, with all but one of the folds being used for the model calibration; the remaining fold is used for validation. We could repeat this k -fold process several times, each time using a different random sample from the data set for model calibration and validation. This allows one to derive distributions of the validation statistics efficiently to assess the stability and sensitivity of the models and parameters. A variant of k -fold cross-validation (CV) is spatial cross-validation where, instead of random subsets of data to act as the different folds, the data are clustered spatially into groups (which we can think of as folds to keep with the general idea).

Quantifications of uncertainty

It is relatively easy to quantify the accuracy of a digital soil map using a set of soil observations set apart from the spatial modelling process for this purpose. A range of statistical tests is available and provides a global appraisal of model performance: that is, they typically cannot tell us anything about the performance of a model at a specific location in the prediction area.

On the other hand, the local appraisal of a model's performance can be done through examination of uncertainties if they are available. Such uncertainties can be quantified at each grid cell across the prediction area and are often expressed in the form of a prediction variance or prediction interval for soil attributes, or even probability estimate for soil classes or exceedance thresholds (Fig. 1).

Uncertainties may be computed with a range of methods. For example, it is relatively straightforward to compute the kriging variance with geostatistics in the case of purely spatial models of soil variation. Minasny et al. (2011) demonstrated a model-based Bayesian approach, while Bayesian networks (Taalab et al., 2015) offer a more expert-driven approach.

Machine-learning methods, and particularly those based on iterative resampling and boosted model fitting, can provide empirical estimates of uncertainty. An example here is the quantile regression forest algorithm that was used in France by Vaysse and Lagacherie (2017).

Methods based on model perturbation through data resampling or bootstrapping have been shown to be effective for quantifying model uncertainties, particularly where the number of model parameters is high, or for very large mapping extents the use of model-based geostatistical approaches is computationally prohibitive. Malone et al. (2011) demonstrated another empirical approach which is based on data resampling and fuzzy k -means with extragrades.

In quantifying prediction uncertainties, we explicitly acknowledge that a digital soil map is not free from error. A major source of error is the sparseness of soil data, both in the landscape space and the attribute space. Often the uncertainty created by this error is of a magnitude that would preclude the use of a digital soil map in many situations where fine precision is a requirement. Consequently, decisions or policies developed based on mapping need to be made with a certain amount of risk, although the risk can often be quantified. To reduce this risk, the uncertainties may be used to prioritize resources for data collection or direct the application of alternative modelling approaches to improve digital soil maps and reduce uncertainty.

Fig. 1 Variability of AWC at 0–10 cm, 30–40 cm and 80–100 cm across the Edgeroi study area. Lower prediction limit (1), DSM final prediction (2), and upper prediction limit (3). This figure is an example of presenting digital soil map uncertainty in terms of a prediction interval with an expressed level of confidence (here 95%). These estimates are derived for every mapping pixel where one can relatively easily distinguish areas of high prediction certainty (lower prediction interval range) from low prediction certainty (high prediction interval range). From Malone BP, McBratney AB, and Minasny B (2011) Empirical estimates of uncertainty for mapping continuous depth functions of soil attributes. *Geoderma* 160: 614–626 and from <https://www.sciencedirect.com/science/article/pii/S0016706110003666>, Fig. 9.

Nuances of digital soil mapping

Knowledge-based inference and mechanistic modelling for digital soil mapping

An alternative to purely empirical modelling is knowledge-based inference. Knowledge-based inference enables the digital soil mapper to integrate expert knowledge into the mapping process. One of the best known knowledge-based tools is the Soil Land Inference Model or SoLIM (Zhu et al., 1997). SoLIM allows an expert to create membership functions manually that describe the presumed relationship between specific soil types and a range of environmental and topographic variables. With these membership functions, the expert can make predictions of soil type or properties at unobserved locations by a weighted estimate that is based on an environmental similarity score for each soil member. Subsequently, the appealing concept of fuzziness between soil objects is maintained, as well as some quantitative means for assessing the uncertainty of mapped predictions.

In similar work, Bui (2004) pointed out that the soil map legend, which is a representation of the distilled knowledge of the soil surveyors' mental model of soil variation across a mapping domain, contains valuable and important structured language that can be used for automating soil mapping if spatial cover of environmental predictors are available. Probably the closest empirical relative to this approach is the decision tree type model, where data are recursively partitioned to minimize some predictive variance.

The idea of utilizing existing soil maps in new, quantitative ways has also found application in the spatial disaggregation of soil map units, where the information contained in these map units can be downscaled to make spatial predictions of the map units' constituent soil types. This can be further enhanced by the incorporation of expert elicited rules about specific soil–landscape relationships that occur across the study area (e.g. Vincent et al., 2016).

Bayesian networks, described by Taalab et al. (2015), also enable the operator to include expert knowledge explicitly. They are also able to be tuned empirically. The methodology first requires the need to express prior knowledge, in the form of probabilities, about the interaction between a target variable and a set of environmental covariates. With these prior probabilities together with Bayesian inference, one can estimate either continuous or categorical variables and then use the derived posterior probabilities as a quantitative measure of uncertainty.

Structural equation modelling (SEM) has its roots in social sciences research and Angelini et al. (2016) have demonstrated its application to digital soil mapping. It enables the integration of empirical information with mechanistic knowledge by deriving the model equations from known causal relationships, while estimating the model parameters using the available data. This approach necessitates a thorough understanding of soil processes. Moreover, these models can predict many soil properties simultaneously, while preserving the relationships between them. The recognition that soil characteristics are not independent variables, which is how they are treated in most DSM model applications is a welcome advancement to DSM. In data science and machine learning, however, advances are continually being made and have been demonstrated by Wadoux (2019) who used a convolutional neural network model for simultaneous prediction of soil texture, organic carbon, pH, and nitrogen across France. This purely empirical model, had the advantage of quantifying prediction uncertainties, which is a general requirement for DSM and to date has not been investigated for SEM.

The future directions of DSM are likely to entail a deeper integration with soil pedology either by pure- or semi-mechanistic approaches like those described above. Ma et al. (2019) reviews the literature on this and provide insight on how both pedology and DSM can be enriched with knowledge and ideas from each science domain.

Space–time modelling

The spatio-temporal modelling of dynamic soil properties such as soil carbon and soil moisture (plant available water) necessitates an integration of process-based knowledge and empiricism and is at the frontier of DSM research. To date most spatio-temporal models of soil carbon are based around space-for-time substitution models (Gray and Bishop, 2019), where a projection of soil change because of climate or landuse change can be calculated readily. Dynamic modelling such as through RothC (soil carbon model) and biomass growth models for more explicit accounting of the biogeochemical processes underpinning soil organic carbon spatio-temporal variability have been trialled (Lee et al., 2020).

Similarly, a better understanding of the spatio-temporal controls of soil moisture variation for real time estimation and then its forecasting, and mechanistic understanding of soil–water dynamics is paramount. Ensemble Kalman filtering is one of the favored approaches for this type of work and its application in an agricultural setting has been demonstrated by Huang et al. (2017).

Soil depth functions and digital soil mapping

Soil survey, soil classification and conventional mapping of soils consider soil as a three-dimensional (3-D) entity or body. Most initial DSM research tended to focus only on the 2-D sense of this general concept where predictions of soil property variation were made for single depth intervals or horizons (and predominantly only from the topsoil).

It is important to attempt to map the variation of soil properties in both the lateral and vertical dimensions. For carbon accounting and understanding the carbon sequestration potential of soil, determining the amount of water soils can hold across a field or watershed, determining the depth to an impeding layer for crop growth across a farm, and investigations of soil acidity, will require some understanding of how soil properties vary with depth.

Ponce-Hernandez et al. (1986) in Malone et al. (2009) suggested that soil properties vary more-or-less continuously with depth. The variation is often anisotropic for certain properties such as carbon and soil texture which may be the result of land use activity or the gravitational vector of profile weathering and development or both. Exceptions to continuous soil property variation with depth is where there is strong anthropogenic (cultivation, removal, and replacement of soils), geologic (contrasting parent materials), and pedological (the development of clear and abrupt soil horizons) forcing for which sharp discontinuities in the depth distribution of soil properties will occur.

Empirical functions describing the depth distribution of soil properties include linear and polynomial functions, exponential and logarithmic functions. Asymmetric peak functions (Myers et al., 2011) and smoothing splines are further depth functions. A special case of the smoothing spline is the pycnophylactic (mass preserving) type as investigated by Bishop et al. (1999) in Malone et al. (2009). Mass preserving splines model the continuous variation of soil properties with depth while maintaining the average of the observed property through the observed horizons or layers. The proviso for a 'good fit' is that numerous observations at regular depths are required. For attributes such as soil organic carbon, it is necessary to have observations close to the surface to avoid over-estimating the contents in the very top few centimeters. Conversely, for some contaminated undisturbed soils with retained elements such as lead (Pb) observations close to the surface are necessary to avoid 'diluting' the effect of the large concentration at the surface.

The coupling of soil depth functions with DSM seems an intuitive advance toward understanding soil variation in all its spatial dimensions. A study by Minasny et al. (2006) reported in Malone et al. (2009) used the negative exponential depth function to describe variation in soil carbon concentration with depth in the Edgeroi area, Australia. The authors modelled the parameters of the exponential function using a modified neural network approach, then predicted parameters of the exponential function over the whole area, which enabled them to calculate the carbon distribution within the profile and the storage of carbon at any depth.

One of the limitations of using equivalents of the negative exponential depth function is that the function is only useful for certain soil properties, such as soil organic carbon, that naturally have that type of anisotropic variation down the soil profile. Polynomial soil depth functions also need to be considered carefully because the value at one depth will also affect the fit of the curve at other depths.

Malone et al. (2009) described a regression kriging approach using neural networks coupled with mass-preserving splines for mapping available water capacity and soil carbon stocks in Australia. The approach is performed in two steps with the first being the standardization of depth intervals given a collection of soil profile data with the spline. Integrating the spline for the specified depth intervals, for example 0–5 cm, 5–15 cm, 30–60 etc., an average value was defined for each depth for each soil profile. Not only are these values the predicted means for a specified depth interval, but they are also parameters of the spline function that can be used for subsequent refitting and soil information interrogation. After the splines are fitted, for each specified depth interval a spatial model is fitted which is then used for mapping. With such a coupling of depth function and DSM, Malone et al. (2009) were able to generate scenarios such as the depth at which the cumulative total of soil carbon was equal to 5 kg m^{-2} among other queries (Fig. 2).

Fig. 2 Maps of scenario-based queries by Malone et al. (2009) in the Edgeroi district in northern New South Wales, Australia. (A) Depth at which soil carbon decreases to below 1%. (B) Depth at which cumulative total of soil carbon equals 5 kg m^{-2} . (C) Depth at which cumulative sum of AWC is 100 mm. From <https://www.sciencedirect.com/science/article/pii/S0016706109003255>, Fig. 9.

Poggio and Gimona (2014) describe a one-step approach to 3-D digital soil mapping using a hybrid generalized additive model (GAM) for carbon stocks in Scotland. One-step approaches are appealing because they reduce the complexity of workflow. With the Poggio and Gimona (2014) approach they avoided standardizing soil prediction depth intervals i.e. they used the observed values, and then modelled the 3-D trend in soil variation with a GAM and an associated 3-D smoother with related covariates. The one-step approach was also appealing to Orton et al. (2016), who introduced an area-to-point kriging methodology. This model could include all the data in one statistical analysis, and importantly maintained the integrity of the sample support of the soil profile data as well as providing an explicit methodology for quantifying the uncertainty of the fitted soil depth function.

Kempen et al. (2011) developed a depth function that combines general pedological knowledge with geostatistical modelling. They modelled the distribution of soil organic matter content based on typical horizons from 10 soil types. Five depth function building blocks were defined, and for each soil type the depth function structure was obtained by stacking a subset of modelled horizons. The parameters of the depth function for each of the horizons were interpolated using a geostatistical procedure that combined environmental information. While pedologically the most appealing approach, the horizon depth function method of Kempen et al. (2011) could be limiting because its application is limited to the spatial extent in which it was developed, or in similar landscape contexts or soil types.

Generalizing the practice of digital soil mapping

While most applications of DSM are based on using observed soil point data coupled with environmental covariates and a spatial predictive model function, it is certainly not restricted to this process. For example, some previous discussion of soil map disaggregation has been made where mapping units are disaggregated into their constituent classes or series whose spatial pattern is determined by a spatial prediction function.

Before exploring that concept in further detail, it is worth pointing out the various possible scenarios that could be encountered for DSM. They are described by Minasny and McBratney (2010) who presented a decision tree for DSM methodology based on the nature of available legacy soil data (Fig. 3). This tree was proposed as a general framework to aid the delivery of a digital global soil map. It can be viewed as guidance to practitioners in “what do I do?” situations. Once the practitioner has defined an area of interest and assembled a suite of environmental covariates for that area, depending on what available data there are to use, there are suggested approaches that could be implemented. The most common approach is scorpan kriging which can be performed when there are only point data, but can also be used when there are both point and map data available. The idea here is that scorpan

Fig. 3 Decision tree of digital soil mapping approaches. Adapted from Minasny B, and McBratney AB (2010) Methodologies for global soil mapping. Fig. 4 Model averaging outputs from [Malone et al. \(2014\)](#). Model averaged digital soil maps of soil pH for the 0–5-cm depth interval across the Dalrymple Shire, QLD, Australia. These maps were produced using Granger–Ramanathan (GRA) model averaging, that both corrects bias and preferentially weights inputs based on comparative model accuracies. Inputs were a soil pH map with estimates from using point-based digital soil mapping (scorpan-kriging) and from disaggregated conventional map approaches (DSMART + PROPR) described in [Odgers et al. \(2014, 2015\)](#). The center map represents the combined prediction, while the left and right maps respectively are the 90% lower and upper prediction limits. From <https://www.sciencedirect.com/science/article/pii/S0016706114001906>, Fig. 5.

kriging and soil map disaggregation are fused through a combinatorial approach such as model averaging. [Malone et al. \(2014\)](#) exemplified such a procedure in an area of Queensland, Australia (Fig. 4).

The options are quite different when only soil map information is available. Consider that the quality of the soil maps depends on the scale and subsequent variation in soil cover; such that smaller scale maps e.g., 1:100,000 would be considered better and more detailed than large scale maps e.g. 1:500,000. The elemental basis for extracting soil properties from legacy soil maps comes from the central and distributional concepts of soil mapping units. For example, modal soil profile data of soil classes can be used to create soil property maps quickly. An early example of this is the multilayer soil characteristics dataset for the conterminous United States (CONUS-SOIL), which has been and continues to be used in many climate, hydrology and land surface models ([Miller and White, 1998](#) in [Odgers et al., 2014](#)). Where mapping units consist of more than one component, we can use a spatially weighted means type method, i.e. estimation of the soil properties is based on the modal profile of the components and the proportional area of the mapping unit each component covers. As a pre-processing step prior to creating soil attribute maps, it may be necessary to harmonize soil mapping units (in the case of adjacent soil maps) and or perform some type of disaggregation technique to retrieve the map unit's component information.

More recently, research into the spatial disaggregation of soil map units has emerged as a means of downscaling choropleth soil mapping. For example, the DSMART algorithm ([Odgers et al., 2014](#)) spatially disaggregates a choropleth map by iteratively resampling it to create a series of classification trees that create realizations of the potential soil class distribution. The realizations of soil class distribution are merged to estimate the probabilities of occurrence for all the soil classes in the choropleth map area. These probabilities together with modal soil profile characterizations associated with each soil class can then be integrated to derive soil attribute maps (such as pH, soil texture fractions etc.) as shown by [Odgers et al. \(2015\)](#). Modifications to DSMART by explicit inclusion of soil–landscape relationships, which assist and or constrain the allocation of likely soil types within a soil mapping unit, has been demonstrated with some success in the French region of Brittany ([Vincent et al., 2016](#)).

How do we do digital soil mapping in an area that does not have any soil data? In such areas ('recipient' areas) it may be possible to extrapolate using a model that was constructed in an area with available soil data (a 'donor' area). The rationale, called homosoil ([Mallavan et al., 2010](#)), is that if the recipient area is sufficiently homologous to the donor area with respect to the strength and expression of soil forming factors then extrapolation is feasible without an unacceptable degree of uncertainty. Identification of potential donor areas is based on computation of the similarity to the recipient area in terms of the relevant soil forming factors.

Operationalization of digital soil mapping

Since the end of the first decade of the 21st century, DSM has matured as a science and in some places worldwide is used as an operational tool for soil mapping agencies. In Australia for example, [Kidd et al. \(2020\)](#) describe the evolution of DSM from research undertakings within governmental agencies to a nationally coordinated program to deliver a [freely available, comprehensive National digital soil information system](#) and an active community of practitioners in both public and private funded organizations. Similar experiential pathways have been encountered elsewhere and new national, continental and [global](#) digital soils information facilities have also emerged similarly ([Chen et al., 2022](#)).

Not all operational work has focused on the development of digital soil maps *ab initio*. For example, government-sponsored work has led to the updating of legacy maps using digital techniques (Kempen et al., 2009). Agencies in other jurisdictions are working to integrate digital soil mapping methods with existing survey procedures. The relatively recent phenomena of national and global scale DSMs have been motivated through coordinated efforts by a series of international conferences and the GlobalSoilMap initiative (Arrouays et al., 2020a).

The GlobalSoilMap initiative

Soil mapping at the global extent is not a recent or new endeavor. The FAO–UNESCO soil map of the world was the first world soil map published (1981) that used a single map legend which accounted for the global diversity of soils. In around 2006 a proposal for a new global grid of the most important soil functional properties was made. Later that year, the [GlobalSoilMap.net](https://www.globalsoilmap.net) consortium was formed to create a new, high-resolution digital soil map of the world using state-of-the-art and emerging technologies. The consortium was inspired in part because of “policy-maker’s frustrations” about not being able to get quantitative answers to questions such as how much carbon is sequestered or emitted by soils in a particular region? Or, what is its impact on biomass production and human health? Or how do such estimates change over time?

Technical specifications of the GlobalSoilMap are given in the specifications document (Arrouays et al., 2014). This publication articulates not how digital soil maps should be created, but the standard to which they should conform to permit collation for the assemblage of a global product. This specification promotes innovation in digital soil mapping practice and recognizes that practitioners may prefer certain methods, and that different methods may perform better in different environments.

Key aspects of the specifications include the spatial entity such as the data support and resolution at which maps should be created, the soil properties to be predicted, the date associated with their prediction, and an explicit communication of the prediction uncertainty and accuracy. Other aspects include documentation standards and reproducibility, and the data release policy.

The initial organizational and collaborative structures brought about by the GlobalSoilMap initiative no longer exist, but it has left a lasting impact as exemplified by national soil mapping efforts, together with a large and active international research community which supports new, upcoming and seasoned scientists through training and education in the ‘how’ and ‘to’ of doing DSM (Kidd et al., 2020). In 2016, the International Union of Soil Sciences created a Working Group (WG) named “Global Soil Map” to maintain this active international community. The Pillar 4 “Soil Information” of the UN–FAO Global Soil Partnership actively promotes country-based DSM activities and now includes the above mentioned WG in its scientific committee (Arrouays et al., 2020a).

Uses and users of digital soil mapping

As outlined earlier, the GlobalSoilMap effort aimed to provide high-resolution soil attribute maps that can ultimately be used in a variety of applications. These maps can provide soil inputs (e.g. texture, organic carbon and soil-depth parameters) to models predicting land-cover changes in response to global climatic and human disturbances. Here, we will discuss a few examples.

Maps of more readily available soil properties can be used to estimate other more costly, or difficult to measure soil attributes. For example, Ballabio et al. (2016) used soil texture maps (%clay, %silt and %sand) created using topsoil data from the European Land Use and Coverage Area frame Survey (LUCAS) to derive maps of bulk density, USDA soil texture classes and available water capacity. These soil attributes may then be used to assess the C sequestration potential of topsoils (bulk density), assess the soil water holding potential of agricultural soils for informed soil management, or estimate soil compaction hazards (texture classes).

Similar research has been conducted in France to estimate potential C sequestration and C storage (Chen et al., 2018) and available water capacity (Román Dobarco et al., 2019). More recently, French GlobalSoilMap products were used in combination with modelling to assess the feasibility of reaching the 4 per Mille target of increasing C stocks in soils (Martin et al., 2021).

High resolution soil attribute maps can also be used for monitoring and forecasting biophysical properties. More explicitly, these soil attribute maps may be used as input soil information to drive physical systems simulation models (e.g. crop simulation models such as APSIM) or for land suitability assessment, or more broadly defined as digital soil assessment.

An example of the use of fine-resolution 3-D soil-attribute maps is land suitability assessment that contributed to the GlobalSoilMap effort in Australia (Kidd et al., 2015), and was derived for Tasmania, Australia. Here, digital soil assessment was used to provide information on the agricultural suitability of land for 20 crops (perennial horticultural, cereal and vegetable crops) in a new irrigation scheme ‘Water for Profit Program’ commissioned by the Tasmanian state government. Together with 3-D soil-attribute maps (80 m × 80 m), climate grids (e.g. growing degree-days and frost risk) were applied to a range of defined enterprise-suitability rulesets to produce enterprise suitability maps. All maps created are stored on a publicly available spatial internet portal (Land Information Services Tasmania, LISTmap <https://www.thelist.tas.gov.au/app/content/data#>) and can be used interactively to perform a range of land management based assessments, such as identifying limiting soil and climate conditions. Outputs also include an enterprise versatility index; and the highest-valued agricultural land with the highest earning potential for individual commodities can also be identified.

Soil security to maintain soil function in supporting food and fiber production together with ecosystem balance is widely reported to be under threat due to human impacts and population increase. Consequently, there is growing activity throughout the world to measure and monitor soil resources (Arrouays et al., 2021), or more specifically the functions and services that soils provide directly and indirectly (Adhikari and Hartemink, 2016 in Aitkenhead and Coull, 2019). Digital soil mapping and

assessment can provide comprehensive and objective assessments of attributes including soil carbon stocks, and assessment of the potential of soils to store more carbon, through to explicit assessment of soil ecosystem services (Aitkenhead and Coull, 2019). It is expected that practitioners of DSM will soon respond in better and more creative ways to end-user requests for soil and soil-related information for these more general assessments of ecosystem function, rather than concentrated practice of creating estimated soil property maps as an end in itself.

Conclusions

Digital soil mapping is an effective tool for producing nuanced soil information. This information can be used in various ways, from understanding the status and condition of soils in a highly granular way, to aid in the planning and deployment of strategic land management practices and policies.

Scientifically, the incorporation of mechanistic soil processes into digital soil modelling is an innovation which should be given greater focus. Recent work with soil carbon, water and texture have been important contributions, together with structural equation modelling which provide explicit characterization of soil processing into the model framework. Digital soil mapping should not just become a machine learning exercise, and there are clear examples and experiences of the pitfalls of relying solely on machine learning algorithms to do the process in a thoughtless manner, and without rudimentary quality control mechanisms (for example, does the spatial pattern of the predictions make sense in a soil–landscape pedological context) of the outputs that are generated (Arrouays et al., 2020b).

There will be a widening and deepening role of public–private partnerships in the development and application of digital soil mapping to address serious environmental issues. For this, the process of digital soil mapping should not be considered a static task, but rather viewed as a dynamic process where efforts are continually revisited, updated, and improved where possible. Efficient strategies need to be developed to ensure the best use of available funding resources for the most gain.

Ultimately, soils are our most valuable natural resource. Digital soil mapping and assessment provide the tools and objective abilities to characterize and monitor the status of this resource better. Digital soil mapping is playing its part and will continue to be engaged in efforts throughout the world to ensure that we live on this planet in a more sustainable way.

Abstract

Geographic information systems (GIS) are essential to facilitate digital soil mapping (DSM) and soil modeling (pedometrics) and have moved from personal desktop, client-server, to cloud-based geodata and geoprocessing engines. Soil information systems disseminate geographic soil data as vector-based map units or grids. Artificial intelligence (AI) geospatial soil models provide excellent predictive capabilities, though AI cloud-based GIS and geotechnologies have raised numerous ethical concerns. Soil and environmental geodata support pedometrics applications and soil as well as land and Earth simulation models to assess soil health, soil security, soil ecosystem services, soil erosion, global climate change and carbon sequestration, and other broad topics of global importance.

Key points

- Geographic information systems (GIS) and digital soil mapping (DSM) are closely linked.
- GIS have moved from personal desktop, client-server, to cloud-based geodata and geoprocessing engines.
- Soil information systems provide geographic soil data associated with vector-based map units or grids and soil profile data.
- Artificial intelligence (AI) soil models use machine learning and deep learning algorithms that are often superior in terms of predictive capabilities and accuracies compared to more traditional quantitative soil models derived by geostatistics, regressions, or hybrid approaches.
- Ethical concerns related to geodata privacy and AI geospatial soil models urgently need to be addressed given the fast development in geo- and agro-technologies and AI.
- Soil-environmental geodata support pedometrics applications and soil/land and Earth simulation models to assess soil health, soil security, soil ecosystem service, food security, global climate change and carbon sequestration, and other broad topics of global importance.

Introduction

The term ‘geographic information system’ (GIS) has become synonymous with a wide range of computer applications, technologies, and scientific methods related to the use of geospatial information. The origin of GIS can be traced back to early electronic mapping tools, such as the Canada Geographic Information System (CGIS) developed in the mid-1960s. However, limiting the definition of GIS to a spatial visualization tool would be to disregard its current scientific and technological capabilities, as well as the huge expansion of GIS applications in science, technology, engineering and mathematics (STEM) disciplines, public administration, and economics. A contemporary definition of GIS was provided by Bolstad (2019) stating that a GIS is a computer-based system to aid in the collection, maintenance, storage, analysis, output, and distribution of spatial data and information. The GIS system may reside on a personal computer, be implemented in the form of client-server architecture, or completely reside in the cloud (internet). Driven by the rapid growth of computer technologies on the one hand and globally increasing demands for spatial information on the other, GIS has evolved more recently from a digital mapping facility into a fast-growing spatial science technology. The amalgamation of computer-assisted cartography with database technologies and growing capabilities of analyzing data across different layers in an object-oriented programming environment has generated current GIS management technology for capturing, analyzing, and modeling spatial data. Such GIS platforms facilitate the study of geospatial environmental problems such as soil degradation, global climate change, soil carbon sequestration, soil health, soil security, and food security. Specifically, GIS has become an indispensable tool for quantitative applications in soil science, specifically in the disciplines of pedometrics and digital soil mapping (DSM).

Geospatial technologies have undergone a revolution in development in terms of data collection, operational management, mobility of public sharing of geospatial data, and interconnected GIS workspaces (Fig. 1). Advancements in high-precision and high-accuracy geo-surveying of soil and environmental data, specifically global positioning systems (GPS) that are used for geo-referencing of data (i.e., the identification of geographic coordinates such as latitude and longitude, or x and y coordinates) and satellite technology, have amplified the trend towards finer spatial resolutions of geodata products. The management of soil-environmental data collected through geotechnologies is facilitated by GIS that enables the storage and processing of vector data—including (i) point-specific data such as soil attributes for different genetic horizons or layers (Fig. 2a), (ii) pedon or site-specific data (Fig. 2b) as well as (iii) polygons such as soil map units (Fig. 2c), and (iv) voxels such as 3-D soil layers (Fig. 2d)—and raster (grid) data to capture soil properties or soil taxonomic variables. An example of gridded soil organic carbon (SOC) predictions for Florida, United States are shown in Fig. 3. Soil grids have become more common due to the ease, speed, and versatility of raster-based GIS analysis. Soil-environmental data collected as part of research projects are typically stored on personal geodata servers (PCs or organizational servers), while publicly shared geospatial data are stored and disseminated in online geodatabases or geoportals in the cloud. Examples of global geoportals are the Geospatial Google Earth Engine, Amazon Geospatial and Amazon Web Services (AWS), and the Environmental System Research Institute (ESRI) ArcGIS Online Open Data.

Earlier GIS databases and processing applications adopted a computer client architecture using commercial GIS software such as ESRI's ArcGIS Desktop, IDRISI, Earth Resources Data Analysis (ERDAS), MANIFOLD, and multiple open GIS such as the open source QGIS and the freely available System for Automated Geoscientific Analyses (SAGA) GIS. While earlier and some contemporary GIS applications run on PCs the trend is to move geoprocessing into the cloud in which an increasingly amount of geodata already reside. Examples for global cloud-geospatial processing engines are the Google Earth Engine, Amazon Elastic Cloud Compute Services (Amazon EC2), and ArcGIS Online Data. Importantly, these types of cloud-based platforms combine versatility, security, and computational speed to support advanced artificial intelligence (AI) algorithms—machine and deep learning—in support of pedometrics and DSM. Cloud-based GIS portals and processing engines also offer GIS web services and map publishing applications. Hence, the public sharing of digital soil map products and soil models facilitated by the cloud has accelerated the sharing of geospatial soil information with end-users and stakeholders. The coding of soil models in open source R and Python languages to assess soil properties, indices, services, or functions has further contributed to popularize the movement of GIS into the cloud.

The exponentially growing markets of smart phones and mobile devices have spawned the development of mobile GIS applications and mobile soil tools and 'apps,' for example the SoilWeb and mySoil apps (Fig. 1). According to Herrick et al. (2017), the benefits of mobile soil apps, such as the Land-Potential Knowledge System (LandPKS), are manifold. First, these mobile technologies make it easier to collect, store, access, integrate, and interpret the soil and land inventory and environmental monitoring data from a geographic perspective. Second, the apps provide in-built applications developed by experts that help users with little or no soils knowledge to map and interpret soils. Third, the tools and apps allow users to share and compare their data easily with others. Fourth, informed decision-making and optimal soil/land management is supported by AI and other quantitative model algorithms that are built into the mobile apps and tools. These decision-support tools often connect with larger public soil-environmental geodata sources that have accumulated in the cloud and are likely to increase as new data are continuously acquired through monitoring. This shift from personal data acquisition and privacy of data towards public and open data policies are advantageous for globalizing soil-environmental geodata and improving 'smart' decision-making on how to use and manage soils and the land efficiently to meet sustainability and food and soil security goals.

Ethics and privacy issues with regard to the public sharing of geospatial data and use of GIS have sparked a critical debate, specifically when public cadastral and land owner data are involved (Blatt, 2012). The misappropriation of private landowners' data (e.g., farm or ranch data) that are shared as public data are prone to misuse by corporate industries. Privacy and data security concerns also raise questions when soil and land data are used to overregulate common good resources, for example, by imposing environmental management regulations, taxes, or fines on landowners. Another ethical concern about open multi-user shared geospatial soil-environmental data and models pertains to the lack of protective data sharing policies of global as well as national institutions and global researcher groups that have tended to incorporate local and regional soil-environmental data and models without providing appropriate credit, acknowledgement, or compensation. This is particularly unfortunate in the soil science domain where manual labor, time, and costs are high for field data collection, investments in instrumentation and technology, laboratory analyses of soil samples, and data entry effort.

In the following sections we will explore GIS applications to soils focusing in more depth on (1) soil-environmental geospatial data acquisition, (2) GIS-supported digital soil mapping, and (3) the role of GIS in pedometrics, simulation models, and decision support systems.

Soil-environmental geospatial data acquisition

The conceptual frameworks underlying pedometrics and DSM have been rooted in soil-factorial models that relate soils and soil-environmental factors, assess the spatial variation of soils within a region, or simulate pedogenic and ecosystem processes (Grunwald, 2006). These contemporary quantitative soil-factorial models are rooted in Jenny's and Dokuchaev's mental models of soil formation that link soils to state factors, such as climate, organisms and vegetation, relief, and parent material. For all types of soil-landscape model it is essential to acquire soil-environmental data for a region or area of interest (AOI). Typically, these

Fig. 1 Geospatial technologies used in soil science covering the spectrum from field data collection in the soil-environmental systems to the publishing and sharing of maps.

Fig. 2 Geographic representations of soils in the form of (a) site-specific pedons with genetic horizons or fixed-depth layers at specific sites, (b) continuous soil data along vertical profiles derived by splines or other interpolation methods, (c) soil taxonomic or soil property polygon maps with map units providing discrete boundaries, and (d) 3-D soil representations. Image, data, and source credits: (a) Houston soil profile, Very-fine, smectitic, thermic Oxyaquic Hapluderts. Natural Resources Conservation Service, United States Department of Agriculture. Public pedon photo gallery: https://www.nrcs.usda.gov/wps/portal/nrcs/detail/soils/survey/office/ssr7/profile/?cid=nrcs142p2_047981; (b) The map shows soil organic carbon (SOC) stock at 0–100-cm depth derived for 15,436 soil profiles in the contiguous United States of America. The SOC stocks for each profile were derived by splines with the equal-area smoothing spline function using horizon-based SOC and bulk density measurements. The graph on the left shows a fitted spline derived from SOC horizon measurements for a randomly selected site of the whole dataset (courtesy of S. Grunwald with contribution by B. Cao). soil-environmental data are harmonized into a spatio-temporal data hypercube by a wide variety of geospatial technologies, remote sensing, soil surveying, proximal soil sensing, and available public geoportals (Fig. 1).

Prominent spatially and temporally explicit soil-factorial modeling frameworks that use soil-environmental hypercubes to predict or model soils are the SCORPAN model (McBratney et al., 2003; McBratney et al., 2018) and the STEP-AWBH model (Grunwald et al., 2011; Grunwald, 2021; Ma et al., 2019; Thompson et al., 2012). These modeling frameworks consider soil as an integral component of the ecosystem that can be characterized by different spatio-temporal factors (Fig. 4): (1) STEP-factors that are relatively stable across the human lifetime: Soil (S), Topography (T), Ecology (E), Parent material (P); and (2) AWBH-factors that are dynamic in space and across time: Atmosphere/climate (A), Water/hydrosphere (W), Biosphere (B), and Human (H) factors. Each of these factors can be quantified through a set of variables. For example, the S factor can be characterized by soil data such as SOC, soil texture, pH, soil taxonomic class, cation exchange capacity, etc. derived from legacy soil maps or databases, gamma ray sensing, and remotely sensed soil moisture data. The factor A may be populated by climatic data such as long-term average of mean annual precipitation, seasonal variation of minimum and maximum temperature, and long-term solar radiation, while B could be populated by satellite-derived land use/land cover maps, vegetation indices like the normalized difference vegetation index (NDVI) derived from satellite data, biodiversity, and habitat data. The factor H may be populated by variables from the social, cultural,

Fig. 4 Process in digital soil mapping to develop soil prediction maps and models from a hypercube of soil-environmental geodata. The soil-factorial model called STEP-AWBH (described in detail in [Grunwald et al., 2011](#) and [Grunwald, 2021](#)) provides a spatially and temporally explicit framework to characterize the STEP-AWBH factors: Soil (S), Topography (T), Ecology (E), Parent Material (P), Atmosphere/climate (A), Water (W), Biota (B), and Human (H) factors.

economic, and political domains (e.g., greenhouse gas emission data, land management data, and fertilization data). The aim is to populate the STEP-AWBH factors with soil-environmental geodata that influence pedogenesis; and thus, these factors contribute to soil formation in varying degrees. Xiong et al. (2014) exemplified the STEP-AWBH model and multiple AI-machine learning methods in Florida, United States, to develop prediction models for SOC.

The GIS are essential to populate and verify soil-factorial models, geospatial and geostatistical soil models, and (quasi) mechanistic land and Earth system simulation models to store, manage, and harmonize geospatial soil-environmental data. The observation methods described in the following paragraphs are not exhaustive but provide a brief overview of widely used sources to populate soil models.

Aerial photography, which emerged in the 1920s, is still in use for mapping planetary surface features, specifically vegetation; however, aerial imaging has been complemented and stands in competition with satellite technology and drones. The latter enable the collection of targeted ad-hoc high-resolution field data to assess soil deterioration or soil-vegetation stresses caused by multi-hazard disasters, global climate change, or others. The advent of soil and environmental data collected with a variety of fine (submeter to 5 m), medium (5–30 m), and coarse (30 m to 1 km+) spatial resolution satellite images have propelled DSM to produce local, regional, national, and global soil maps and models. There are various satellites that provide global multi-temporal data sets, for example, the Moderate Resolution Imaging Spectroradiometer (MODIS) and Landsat Enhanced Thematic Mapper (LANDSAT ETM+) by the North American Space Agency (NASA), SENTINEL images provided by the European Space Agency, Satellite Pour l'Observation de la Terre (SPOT) by the French Space Agency (Centre National D'Etudes Spatiales, CNES), and RESOURCESAT by the Indian Space Resource Organization (ISRO). Other fine-resolution commercial satellites are GeoEye, RapidEye, WorldView, and Pleiades. These passive remote sensors allow sensing of vegetation, terrain, and the thin layer of surface soil, while active remote sensors, such as RADARSAT with measurements in the microwave region and gamma-ray sensing that can measure the composition of soils and parent material, have greatly enhanced DSM. Satellite-based mapping of soil moisture has been conducted by the Soil Moisture and Ocean Salinity (SMOS) mission, NASA's Soil Moisture Active Passive (SMAP), and others. Light Detection and Ranging (LiDAR) is a remote sensing method that uses light in the form of a pulsed laser to measure ranges (variable distances) to the Earth and has been used extensively to create fine-resolution digital elevation models (DEM), some with sub-meter spatial resolution. Other global DEMs were developed by Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) satellite data, the Shuttle Radar Topographic Mission (SRTM), the high-resolution DEM of the European Copernicus program (GLO-30 and GLO-90), and the WorldDEM Neo at 5 m pixel spacing. A variety of primary and secondary terrain properties, for example, the terrain wetness index or mass balance index (see Fig. 5), can be derived from DEMs and are valuable input data for DSM (Conrad et al., 2015). Fig. 5 exemplifies the mass balance index for the parameterization of slope transfer processes, integrating the universal soil-loss equation (USLE) R-factor and different catchment area parameters (catchment area, catchment slope). Since terrain parameters based on catchment area size tend towards strongly artificial variability in hydrologically homogenous areas such as flat valley bottoms (cf. Fig. 5a), the SAGA (System for Automated Geoscientific Analyses) terrain wetness index (Fig. 5b) applies a slope-dependent, iterative modification scheme to the catchment area size which makes it suitable for the spatialization of hydromorphic soil properties (Conrad et al., 2015).

Traditionally, soil surveying entails soil observations collected with augers from genetic horizons, fixed depth layers, soil pits, or soil cores that are geo-located by GPS (Fig. 2a and b). Soil morphological and taxonomic soil characterization can be completed in the field and data recorded immediately into a geodatabase using portable devices or alternatively field notes are transferred into a geodatabase at a later time. The 'gold standard' of soil survey campaigns is to analyze samples in the laboratory for morphological, physical, chemical, biological, and microecological properties that are subsequently integrated into a geodatabase. Pedon geodatabases, such as the one developed by the Soil Research Laboratory, U.S. Natural Resources Conservation Service for the United States and ISRIC's World Soil Database, provide public access to geo-referenced soil data tabulated for different horizons (Fig. 2a and b).

Field and laboratory soil sensing based on diffuse reflectance spectroscopy, such as visible-near-infrared (VNIR) and mid-infrared spectroscopy (MIR), are now widely used for cost-effective and rapid characterization of the physical, chemical, and mineralogical composition of soils (Viscarra Rossel et al., 2011). An example of the capacity for spectral discrimination among different soils is shown in Fig. 6a. Other in-situ proximal soil sensing methods entail infrared, X-ray fluorescence sensing, field-based gamma-ray sensing, and electromagnetic induction (e.g., Fig. 6b). Hyperspectral datasets from various proximal soil sensors can be integrated into a GIS soil information system. Combining multiple soil sensor data is often beneficial to enhance soil predictive performance on new soil samples or in unsampled locations. Importantly, soil sensors collect continuous data that allow inference on multiple soil properties simultaneously. For example, laboratory grade VNIR soil sensor (e.g., the ASD spectroradiometer range by Malvern Panalytical or the Spectral Evolution spectroradiometer range) spectral data cover the spectral range from about 350 to 2500 nm with 1 nm resolution. Soil spectral models developed by machine learning and deep learning AI algorithms can predict multiple soil properties from the same soil scans. For example, a large spectral library of VNIR spectra was used to predict SOC, pH, cation exchange capacity, CaCO_3 , Fe, clay, sand, and silt content at the global scale (Viscarra Rossel et al., 2016). Soil sensors have become smaller, faster, more accurate, rugged, and 'smart' adopting wireless data transfer or collecting data with portable devices. From a geospatial perspective, each sensed soil sample or core is identified with geographic coordinates, a unique identification number (ID), time stamp, and soil attributes or soil spectral data. Even disparate soil-environmental data collected with different data density, frequency of collection, soil sampling locations and times, etc. can be integrated into relational geodatabases that store different sets of field and laboratory soil data in the form of tables that are connected by key fields (IDs). Geospatial hypercubes of soil-environmental data provide the foundation to compute soil models that are then used to derive estimates, uncertainties, and prediction errors at predicted locations.

Fig. 5 The DEM-based terrain parameterization and estimated soil properties. A review of global soil maps for Earth system models was provided by Dai et al. (2019). Global soil map products include the coarse-resolution Digital Soil Map of the World (DSMW) developed by the Food and Agriculture Organization of the United Nations (FAO/UNESCO). The map shows 4931 mapping units consisting of soil associations. For each of the soil units, estimates are provided of physical (% sand, % silt, % clay, bulk density) and chemical properties (pH, organic carbon, cation exchange capacity, base saturation, C/N ratio, CaCO_3 -content) in the topsoil and subsoil. Apart from the maps of classification units contained in the World Soil Reference Base (WSRB) and tables on soil analyses for every country of the world, an additional soil database was created for global environmental studies, including data on soil moisture storage capacity, soil-drainage classes, and effective soil depth. A corresponding data set of water-holding capacities in a 1×1 grid (latitude, longitude), drawn from original sources to meet the requirements of general circulation model (GCM) experiments. Furthermore, the Global Soil Partnership of the FAO published the Global Soil Organic Carbon (GSOC) Map on a $1 \text{ km} \times 1 \text{ km}$ grid covering a soil depth of 0–30 cm. The Harmonized World Soil Database (HWSD) served to develop the WISE30sec on a 5 by 5 arc-minutes global grid.

Examples of national and large-region soil information systems that provide soil polygon maps, soil rasters, and soil profile databases include the U.S. National Cooperative Soil Survey Soil Characterization database and Gridded National Soil Survey Geographic Database (gNATSGO), Africa Soil Information Service (AfsIS), European LUCAS Soil Database, Australian Soil Resource Information System, Chinese National Soil Profile database, Canadian Soil Information System, soil profiles from the

Fig. 6 (a) Visible-near-infrared spectral scans of soil samples from three different sites in Florida, United States. The spectral scans differed distinctly at sites characterized by different vegetation, soils, and soil organic carbon content. (b) Electromagnetic induction (EM) 38 soil map for a site in southern Wisconsin, Arlington Agricultural Research Station. Valley areas are associated with higher clay and silt loam content, while upslope areas show some eroded soils. Courtesy of S. Grunwald. The EC patterns may be due to the complexity of the landscape in southern Wisconsin where soils are formed in reworked loess that is silt-rich mixed with sand-rich glacial till parent material. Erosion in this landscape is a mix of wind and water erosion leading to some interesting relocation of soil material that is not solely topography driven. In this landscape both erosion and tillage operations modulate EC patterns. (c) Soil organic carbon (SOC) stock in 0–100 cm in the contiguous mainland of the United States of America. The soil grid with 1 km × 1 km spatial resolution was derived by soil predictive modeling using the Boruta algorithm and Random Forest, a machine learning algorithm (courtesy: Grunwald S, Xiong X, Patarasuk R, Ross CW, and Cao B). Soil data source: Natural Resources Conservation Service, United States Department of Agriculture.

SOTER database, and the Brazilian Soil Information System. The Global Soil Map (GSM) is a global consortium that has brought together various global soil grids standardized for six soil layers (0–5, 5–15, 15–30, 30–60, 60–100, and 100–200 cm) and standardized uncertainty assessment. The SoilGrids—global gridded soil information of different versions of soil raster maps (1 km and 250 m spatial grid resolutions) were developed using state-of-the-art machine learning AI algorithms for a variety of soil properties (e.g., pH, SOC content, bulk density, coarse fragments content, sand content, silt content, clay content, cation exchange capacity, total nitrogen as well as SOC density and SOC stock) developed by ISRIC World Soil Information (<https://www.isric.org/explore/soilgrids>, last access: 14 September 2021). The Soil and Landscape Grid of Australia (SLGA) under the auspices of the GSM initiative serves as an example of consistent and relevant digital soil data at the continental scale (HYPERLINK "<https://www.cdw.csiro.au/aclep/soilandlandscapegrid/>", last accessed 2 February 2022).

The real-time below and above ground in-field monitoring of the environment is a fast-growing emergent of smart farming technology. According to Wolfert et al. (2017), Big Data in smart farming entails an integrated system consisting of smart sensing and monitoring of soil-environmental conditions of the agricultural system, sophisticated technology including high-precision GPS, satellite imaging, robots, unmanned aerial vehicles (UAVs), cloud-based event and data management, advanced geo-analysis that entails machine- and human-generated data, and advanced data analytics and interpretation. Innovation possibilities include open farm management with specific apps, remote/computer-aided advice, AI controlled decision-support systems, and regionally pooled data for scientific research. The vision for such integrated agricultural systems is to 'data mine' available geospatial data from geoportals (e.g., satellite data) and fuse them with laboratory- and field-monitoring of soils, crops, livestock, water, and climate to optimize farm management using advanced AI technology. At the core of such data and knowledge integration are geospatial and temporal domains.

Despite the potential for such integrated AI geospatial soil-environmental systems that strive towards real-time sensing of conditions and change of system components, there are also critical voices. Ethical concerns entail the amplified focus and reliance on AI technologies and machine-generated model outputs that lack knowledge discovery, human interpretation, and scientific understanding of the complexity of soil-ecosystems (Grunwald, 2021). The AI-geospatial soil models are sensitive to pseudo ('false') variables, erratic behavior of models due to outliers or misclassified pixels, and may rely on spurious relations between soil-environmental predictor variables and predicted soil properties (Grunwald, 2021). According to Liao (2020), the development of appropriate ethics and morals that value equally human- and machine-generated knowledge and understanding lags behind the rapid speed at which AI-technologies have developed. Tullis and Kar (2021) pointed out that today's large volumes of geospatial data generated by satellite sensors, GPS, and sensing systems have overlooked the provenance of information as a digital record of historical (retrospective) and potential future (prospective) geospatial processes which blurs the lineage and origins of data and subsequently makes geodata vulnerable to misappropriation. Location privacy is a somewhat nebulous geospatial concept, which has been connected to the erosion of privacy of people together with AI surveillance linked to the control and manipulation of people (Mitchell, 2019). Specifically, farmers and land managers who were traditionally considered stewards of the land and soil may face increasing infringement of the privacy of their location as more geodata of soil and the environment are collected remotely and through proximal sensing technologies. Zhao et al. (2020) asked: Can we trust AI to manage geospatial data? Or may AI be implicated in spoofing in geoscience that calls for spoofing detection principles to inform and protect people and society better from the deleterious effects of AI-managed GIS.

GIS-supported digital soil mapping and modeling

Digital soil mapping is tightly coupled to GIS, the latter enabling the management of soil-environmental data, geoprocessing, and map making. Specifically, GIS facilitate the harmonization and population of soil models to predict and or simulate soil properties, classes, indices, functions, and ecosystem services and also visualize outputs. Soil predictions and model performance metrics rooted in soil-factorial modeling based on SCORPAN or STEP-AWBH conceptual frameworks are derived either through in-built geoprocessing functions within the GIS or external applications coded in R, Python or other computer languages that interface with the geodata.

Comprehensive overviews of quantitative methods to model soil properties and soil classes were provided by Ma et al. (2019), and McBratney et al. (2003). Recent reviews of AI machine learning to model soils were provided by Khaledian and Miller (2020) and AI deep learning (artificial neural networks) to model soils by Padarian et al. (2019). A description of various hybrid (mixed stochastic-deterministic) methods (e.g., regression kriging) to model soils can be found in publications by Arrouays et al. (2017) and Keskin and Grunwald (2018).

To exemplify AI machine learning geospatial soil modeling a brief case study is presented. The goal of this study was to model SOC stock in the contiguous U.S. A total of 144,833 SOC and bulk density measurements in genetic horizons collected at 15,881 sites from the National Cooperative Soil Survey Soil Characterization Database (U.S. Natural Resources Conservation Service, NRCS) were retrieved and then interpolated with the mass preserving spline function to derive SOC stock for a depth of 0–100 cm in soil profiles. The SOC stock data were intersected with geospatial STEP-AWBH factors including soils from gSURGO (NRCS), topographic variables such as elevation, slope, curvature, and flow accumulation (National Elevation Model, U.S. Geological Survey), ecoregions (U.S. Environmental Protection Agency), parent material (rock type and gamma ray data from the U.S. Geological Survey), climate data including long-term average annual precipitation and temperature (PRISM climate data, Oregon State University), biotic data such as land cover/land use (National Land Cover Database), NDVI from MODIS, various vegetation-specific variables (Landfire dataset), and soil hydrology such as annual water table depth, available water storage

capacity, drainage class, hydrologic group, and soil moisture from gSSURGO and SMOS. Soil measurements and geospatial STEP-AWBH variables were used to train the soil model (calibration phase, 70% of data) and verify model output (validation phase, 30% of data). Random Forest (RF), one of the most popular machine learning AI algorithms, was used to model SOC stock in the contiguous U.S. The predicted raster map of SOC stock (kg m^{-2}) for 0–100 cm soil depth was produced at a spatial resolution of $1 \text{ km} \times 1 \text{ km}$ grid cells (Fig. 6c). The total SOC stock for the contiguous U.S. was 61.04 ± 10.66 (standard deviation) Pg C (0–100 cm). More specifically, the largest stocks were predicted by the RF model in three areas: Northeastern highland, northern Wisconsin, and northwest coast forest. Of the total stock of 61.04 Pg SOC about 43% (26.35 Pg) was stored in the topsoil (0–20 cm). Performance of the SOC model in calibration mode gave an R^2 of 0.88, root mean square error (RMSE) of $3.73 \text{ (kg m}^{-2}\text{)}$, and ratio of performance of inter-quartile range (RPIQ) of 1.83. In validation mode the SOC model had an R^2 of 0.43, RMSE of 6.99, and RPIQ of 0.96. Overall, of all STEP-AWBH variables SOC stock in the United States was controlled by a mix of soil, ecological, parent material, atmospheric, and water environmental variables (SEP-AW) and to lesser extent by biotic and topographic (T-B) variables.

Role of GIS in pedometrics, simulation models, and decision support systems

Geographic information systems play a similarly important role in DSM and pedogenic, land, and Earth simulation models that aim to simulate soil-ecosystem processes to model the spatial and temporal changes in soils and other environmental properties. These models view soils as a highly dynamic, reactive and controlling geographic entity rather than a static object of inventory.

A wide range of model applications exists in the context of soil carbon sequestration, soil erosion risk, soil degradation, soil health, crop yield and food security, global climate change, soil ecosystem services, and other assessments. All of them discretize a landscape into geographic model units, either polygons or grid cells. The finer is the model unit, the greater is the demand to populate models with fine-resolution soil-environmental data. The importance of GIS also changes; it is best described as a transition process, beginning with its use as a transaction-processing system and technical tool for data management. It then goes on to become an array of scientific analytical methods capable of supporting the basic demands of spatial information science, with the final stage as a decision-support system, with potential uses within a range of applications.

Examples of soil assessments entail the modeling of soil organic matter dynamics in agroecosystems at the landscape scale (Viaud et al., 2010), DayCent and its land surface submodel (Parton et al., 1998), and SOC modeling using RothC (Jebari et al., 2021). An overview of quantitative models for pedogenesis was provided by Minasny et al. (2008) and Stockmann et al. (2011).

With the dual role of soil as a production factor and an interacting and controlling layer within the atmosphere-biosphere-geosphere system, the assembly of soil data is of particular interest in the context of agro-environmental models supporting sustainable development. The momentum of this development is reflected in an increasing number of geospatial soil information systems. Although mostly embedded in primary land or environmental information systems, they show distinctly the technical and scientific specialization required for handling and providing digital soil and soil-related information targeted at sustaining soil health, soil security, and ecosystem services.

Strong dependence on the quality and parameter space of spatially explicit soil data is particularly evident in GIS-based soil erosion risk assessment. In general, models quantifying water erosion as the most severe degradation process in terms of its global distribution and impact are frequently differentiated into block models, covering agricultural plots as discrete modeling entities or spatially distributed erosion models. From an epistemological point of view, however, the differentiation between empirical bottom up and physically based top-down approaches is even more important with respect to distinctly differing data requirements.

Empirical erosion modeling traces back to the famous universal soil loss equation (USLE) developed in the late 1950s by Wischmeier and Smith (1987) to quantify rates of soil erosion on agricultural slopes as a multiplicative function of six environmental variables (the following factors: R, precipitation; L, slope length; S, slope; C, vegetation cover and tillage; K, soil-erodibility; P, erosion-protection). The parameterization of topsoil erodibility in the USLE K-factor considers soil texture (sand and silt percentages, coarse soil content), organic matter content, and classes of permeability of the soil's surface layer, e.g., entailed or delineated from soil taxonomy profiles. With its simplicity, the USLE and its numerous derivatives can be easily implemented in GIS, and until now are the established standards in practical risk assessment of soil erosion.

Empirically based models have limited transferability, therefore, more sophisticated, process-based approaches have been developed, capable of simulating water erosion in a physically consistent manner (e.g., Erosion 3D, Eurosem, and SWAT). Given that environmental threats from fluxes of water driven matter are not limited to onsite deterioration but also affect neighboring ecosystems with plant nutrients and chemical pollutants, GIS-based process modeling increasingly addresses surface runoff to support management decisions to minimize offsite risks. An example of integrated modeling of water erosion and surface runoff implemented in a client-server architecture with Web-GIS interface is given in Wendland et al. (2016). For illustration see Fig. 7.

Physically based models compared to empirical approaches are advantageous in terms of their wider applicability, but place greater demands on the spatiotemporal resolution and quality of input data. This is particularly valid for soil data, which have to be available either as physical soil attributes or as delineated parameterizations. With respect to its use in case studies, management decision support, and particularly in the context of precision farming applications, major requirements concern the spatial resolution; and thus, demand suitable procedures for the high resolution spatialization of soil properties. In this regard, Web-GIS

Fig. 7 Soil erosion and surface runoff in 2014 in the Gehle catchment (North Rhine-Westphalia, Germany). (a) Annual soil erosion rates. (b) Per-field classified surface runoff (shaded) and offsite risk classes (signal colors) for channel segments. Adapted from Wendland S, Bock M, Böhner J, Feise D and Lembrich D (2016) Towards the development of a GIS based Diagnosis-Tool for the spatially-explicit assessment of runoff and erosion risks on agricultural fields. *GeoÖko* 37(3–4): 139–164.

interfaces increasingly used in agriculture offer a promising option to extend existing soil data bases from legacy soil surveys through to the integration of farm level data that improve the spatial representation of soils.

Conclusions

Geographic information systems and technologies have been of critical importance in supporting the collection of soil and environmental data, database management, digital soil mapping, and pedometrics. Specifically, sensor technology, cloud-computing, and AI have accelerated the digitization of soils and simulation modeling of soil processes and change at increasingly finer spatial and temporal resolutions. These advances in technology have stressed data-driven approaches to model soils rather than the discovery of knowledge about natural soils and how people use and value them. As these trends continue in the future there are serious risks that AI and geospatial technologies could be misappropriated, used to control soil-environments, farmers, and land stewards (e.g., agro-technology), applied in unethical ways breaching data privacy issues, and overshadowing provenance and people's relation with the soil. On the other hand, digital soil information plays a profound role in addressing important global dilemmas, such as soil health and security, food security, soil erosion, climate change and carbon cycling, and degradation or even loss of soil ecosystem services and functions.

Acknowledgments

The authors thank Margaret Oliver and Uta Stockman for valuable comments on the manuscript. SAGA GIS development is supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany's Excellence Strategy—EXC 2037 'CLICCS—Climate, Climatic Change, and Society'—Project Number: 390683824, contribution to the Center for Earth System Research and Sustainability (CEN) of Universität Hamburg.

Abstract

Precision agriculture is a management strategy to increase the resolution of agricultural decision-making in response to variability in production. For crop and pasture systems, this variation in production is strongly linked to soil variability. For this reason, improving the ability to measure and map soil variation has been a key factor in Precision Agriculture. This chapter introduces the concept of precision agriculture, provides an overview of the key enabling technologies, with a focus on soil sensing, and discusses the importance of pedometrics and digital soil mapping for decision-making. On-going and emerging links with soil science are also introduced.

Key points

- Precision agriculture is a management strategy to make better decisions at finer spatial and temporal scales than was previously possible
- Site-specific crop management has always been and continues to be premised on managing the variability in soil systems to improve production
- Precision agriculture relies on pedometrics and digital soil mapping to provide the methods and the soil information needed for site-specific crop management.
- Precision agriculture continues to need soil science input to advance.

The emergence of precision agriculture

Precision agriculture (PA) is now a well-known term in global agriculture. But where did the term and concept of PA come from? The current concept of precision agriculture emerged in cropping systems in the late 1980s with the matching of soil fertility maps, which were derived from grid-based sampling of soil properties, with newly developed variable-rate (VRT) fertilizer equipment (Pierce et al., 1994; Stafford, 1996). Using dead-reckoning principles, fertilizer was applied variably to complement the variation in soil fertility. Precision agriculture at this time was often referred to as “farming by the soil.”

At this stage, crop yield monitoring technologies were still in the research phase and satellite navigation systems were unavailable to the general public. Around 1990, commercial receivers became available for civilian access to the USDA's (United States Department of Agriculture) Navstar GPS (global positioning system) enabling rapid and ‘accurate’ vehicle location and

navigation that generated a flurry of activity. This new positioning information was incorporated into variable-rate systems and agri-sensors, typified by crop yield monitors that began to be available in the commercial market (Plant, 2001). By 1993 the USDA's GPS was fully operational allowing the fine-scale monitoring and mapping of yield variation within fields with GPS-enabled on-harvester yield monitors. Linking variable yield data with maps of plant nutrient changes within a field marked the true beginning of PA in broadacre cropping.

As PA technology (crop and soil sensing) improved in response to a growing demand, to be more efficient with inputs and to reduce the environmental impact of production it became clear that grid sampling at the intensity required to characterize the variation in soil and crop properties adequately was prohibitively costly. Consequently, by the late 1990s, there was a strong shift toward 'zone' management. This approach subdivides fields into zones of similar crop response that addressed some of the issues with data resolution while trying to maximize the benefits of differential (variable) crop management (Lark and Stafford, 1997).

The success, and potential for further success, observed in the broadacre cropping industry prompted other farming industries, particularly viticultural and horticultural crops, to adopt PA (Arnó et al., 2009). From the late 1990s, there has been increasing research on non-grain crops. Advances in Global Navigation Satellite System (GNSS) technology since 1999 have opened the door for many other applications apart from variable-rate management, including machinery guidance, auto-steering and controlled-traffic farming (CTF). More recently, lessons learned from PA on data management, implementation and adoption are helping to guide the development of digital agriculture, of which PA is only a component.

Precision agriculture has typically been advocated and employed in developed agricultural systems with higher levels of mechanization (Mondal and Basu, 2009). Applications to developing agricultural systems, including subsistence farming structures exist, but are far fewer (Mizik, 2023). However, the philosophy of PA is just as applicable to small-scale and developing systems, even if the degree of technological innovation is not as great (Cook et al., 2003). While mechanization may be less, management is often more (spatially) intense and can still be spatially varied, provided suitable tools for better decision-making are available. These need to be low-cost, user-friendly and effective (Mizik, 2023). There are now globally increasing levels of disruptive technologies, notably smartphone and tablet technologies, which are providing a platform for PA applications in all types of agriculture systems (Lagos-Ortiz et al., 2018). The key is to have the correct decision-making process for each type of system and for each location, i.e. a ubiquitous platform but a site-specific decision system.

To execute, PA is no longer an agricultural science question. Precision agriculture is about developing systems to gather more or new data and information, and decision systems to process and act within agricultural production systems. It depends on advances in many other disciplines for it to advance. At the core there will always be a need for good agricultural science and good soil science, but this operates around developments in sensing technologies (the domain of electrical and chemical engineers), data management and display (computer scientists), data analytics (bioinformaticians and statisticians) and PA machinery (agricultural engineers). Precision agriculture is a truly multi-disciplinary domain, especially when the social and economic components are added to the technical aspects. With such multi- and inter-disciplinary needs, it is almost impossible for any single individual to have the complete PA skills set. Precision agriculture must therefore exist within collaborative and multi-disciplinary teams, within which diverse groups (or individuals) support and enable each other.

This provides an enormous challenge for the PA community. Agriculture is not always seen as a 'sexy' area to work in. Neither does it command the financial power of many other industries (e.g. defense, mining, finance, etc...) where data analytics and engineering skills are equally sought after. There is a challenge for the PA community to attract and to retain people capable of crossing over between engineering, data analytics and agricultural science, including soil science. This does not require such people to be experts in all areas, but rather to have a fundamental understanding of how the many aspects affect innovations in their main specialty. Biological systems, and particularly intrusive systems, such as agricultural production systems, are not intuitive systems for the application of the pure sciences. It is a highly variable and often changeable environment in which practical applications and trade-offs are needed. This is often difficult for people unfamiliar with agriculture to understand, however it is these people (engineers, computer scientists etc.) that are needed to make PA work.

Defining precision agriculture

Many definitions of PA exist and many people have had different ideas of what it should encompass. From the mid-1990s to mid-2010s, numerous and diverse definitions were proposed. In 2019, the International Society for Precision Agriculture (ISPA) (www.ispag.org) accepted a formal definition of PA after a period of consultation with PA-oriented researchers and practitioners from around the world. The ISPA definition of PA is:

Precision agriculture is a management strategy that gathers, processes and analyzes temporal, spatial and individual data and combines it with other information to support management decisions according to estimated variability for improved resource use efficiency, productivity, quality, profitability and sustainability of agricultural production.

It is important to note that the agricultural community identifies PA as an evolving 'management strategy' to support 'decision-making' with regard to resource use. It is not explicitly linked to information technology on-farm (although many new information technologies will improve decision-making). The decision-making itself could be in response to spatial (changes across a field) or temporal variation (changes through a season or seasons). The inference is that a better understanding of variation at finer spatial

and or temporal resolutions will improve decision-making and provide a wide range of benefits (economic, environmental and social) that may or may not be known or measurable at present.

This definition also refers to 'agricultural production' and not agronomy. The PA philosophy has been most strongly expounded in cropping systems; however, PA can relate to any agricultural production system. Its concepts are equally applicable to animal industries, fisheries and forestry, and in many cases PA techniques are being implemented in these domains without being identified as such. To distinguish PA in cropping systems, where soil variation becomes a more dominant issue in site-specific decision-making, the term site-specific crop management (SSCM) is often used. This is defined as "a form of PA whereby decisions on resource application and agronomic practices are improved to better match soil and crop requirements as they vary in the field" (Whelan and Taylor, 2013).

The overall aim of a PA management philosophy can be simplified as an approach to: (i) optimize production efficiency, (ii) optimize quality, (iii) minimize the environmental impact of production, and (iv) minimize the risk involved with production - all at the site-specific level (Whelan and Taylor, 2013). These objectives are not particularly new, with essays on this topic dating from the early 18th century. What is new is the scale at which these concepts can be implemented and the technology available to support them. Prior to the industrial revolution, agriculture was characterized by small fields, with farmers often having a detailed, 'site-specific,' qualitative knowledge of their production system. The mechanization of agriculture, and economies of scale, from the 1950s onwards has resulted in the latter half of the 20th century being dominated by large-scale uniform 'average' management practices in developed agricultural economies. Technological advances in the late 20th and early 21st centuries, has allowed agriculture to revert toward site-specific agriculture, by providing fine-scale, quantitative production information, while retaining the economies of scale associated with 'large' mechanized operations.

Variability, precision agriculture and the production system

Precision Agriculture depends on the existence of variability, and broadly speaking 'variability in production = PA opportunity' (Pringle et al., 2003). Variation in production exists in both a spatial or temporal context (Fig. 1, Blasch et al., 2020). Spatial variation occurs over a measurable distance, and temporal variation occurs over a measurable time period. Precision agriculture should address both of these, although to date it has focused primarily on the variation in spatial production. Both of these types of variation exist in many different forms and need to be considered from different perspectives, including the type, magnitude and distribution pattern of the observed spatial, temporal or spatio-temporal variation.

The magnitude in both types of variation is defined as the difference between the low and high values of a measured property. The distribution pattern relates to how variation is changing in either the space or time dimension. The management implications of these aspects of variation are diverse and are fundamentally linked to the property being measured. However, there are a few simple generalizations that need to be remembered (Pringle et al., 2003). First, the observed magnitude in the variation should be assessed and considered relative to a threshold level of variation below which it would be uneconomic to attempt to manage it, i.e. if the production cost of site-specific management vs uniform management is greater than the potential benefit (especially from a short-term economic perspective) then it makes little sense to apply PA (Ancev et al., 2005). However, if the environmental benefits of a PA approach could be correctly expressed (and remunerated) in a fiscal sense, then these thresholds should decrease and areas with a small magnitude of variation in production may become suitable (economically viable) for PA management. If spatial variation does not exist, then a uniform management system is both the cheaper and more effective management strategy. Second, the distribution pattern of the variation in production needs to be considered relative to possible management interventions. In spatial terms; the pattern of variation should be considered in relation to the smallest possible treatment area. For example, with variable-rate application of fertilizers this is defined by the size and reaction time of the VRT spreader used. In temporal terms, the pattern of variation relates to the timeliness of interventions at temporally varying management stages during the growing season (or the whole season if relevant). In many situations the magnitude of temporal variation may appear much greater than that of the spatial variation. If the impact of temporal variation on production overwhelms that of spatial variation, then careful consideration needs to be given to whether a uniform or differential management strategy is the optimal risk aversion strategy over time.

Fig. 1 A time-series of yield maps from a field in North-western New South Wales, Australia illustrating the spatial and temporal nature of yield variation within a field, which may be environmentally driven by the soil or imposed by management decisions. The 1997 and 2006 maps show distinct management patterns and the intervening years illustrate differing spatial patterns linked to soil and weather conditions in a given year. The field illustrates the difficulty that growers have in interpreting yield (and other production data) visually. Data supplied by Mr M. Smith and images adapted from Blasch G, Li Z, and Taylor JA (2020) A novel pattern recognition approach for the delineation of yield productivity-stability zones using yield map time series. *Precision Agriculture* 21: 1263–1290.

Fig. 2 A schematic diagram illustrating the shift from a historical, conventional uniform field management strategies, via management unit approaches to a true site-specific management strategy. The required increase in data with these shifts are also indicated. Adapted from an image originally produced by the Precision Agriculture Laboratory, The University of Sydney.

Based on these considerations, PA in crops at present operates mostly on a zonal rather than on a completely site-specific basis (Fig. 2). In practice, existing fields are subdivided based on production and environmental variation into more homogeneous zones (Fridgen et al., 2004). These management zones or management units are then managed uniformly, as if they were an independent field. As technology and knowledge advances PA will begin to approach a truly site-specific management regime, and this is now beginning to be observed in perennial tree cropping systems. For precision livestock farming (PLF), the animal is the real site-specific ‘management unit,’ and is typically the scale at which most PLF actions are performed.

Practical implementation of PA (particularly SSCM)

As outlined in the preceding definition, PA is a continuous management strategy, i.e. it is circular and recurring in nature. It has often been expressed in the form of a quality control cycle, based on the ability to measure production, analyze the data, make a decision and apply an intervention (Fig. 3). For agricultural systems, this cycle has been enabled and driven by the ability to potentially geo-reference any production observation, i.e. locate it in time AND space.

Geo-referencing: Global Navigation Satellite Systems (GNSS) (of which the USDA GPS (Global Positioning System) is the most widely known) are the enabling technology for PA and are now commonplace on farms and within our general lifestyle. The ability to geo-reference production activities provides producers with the option to map and visually display farm operations. More advanced systems have also enabled growers to embrace guidance and autosteer technologies on farms ahead of the general population. This permits machinery to drive along repeatable tracks that minimizes soil compaction, reduces driver fatigue over long shifts, minimizes errors and workplace accidents, and enables more precision and timeliness in production operations. For example, it minimizes overlap and ‘doubling’ of inputs or allows operations to be conducted in light-limiting conditions, such as at night or during fog events. By reducing overlaps, immediate economic gains can be achieved, which are generally in the region of 5–8% of applied inputs. The value of a timely operation is harder to quantify, but can be very high if sowing or fertilizer windows are missed due to adverse weather.

Production, Soil and Climate Monitoring: Many sensors and monitors already exist for in-situ and on-the-go measurement for a variety of production, soil and climate variables. The majority of PA research has been directed at identifying how to use the output from these sensors to improve production. These sensors can be deployed remotely (e.g. satellite systems), proximally (e.g. on farm machinery or animals) or as static systems (e.g. weather stations). They can operate on-the-go and/or log data for future analysis.

Attribute Mapping: Agri-environmental sensors often produce large, intensive data sets. These are operational data sets, often irregularly spaced and containing errors or artifacts associated with production effects. These data need to be ‘cleaned,’ processed and interpolated before they can be used for effective decision-making. Since the start of PA, statisticians have been researching accurate ways of describing and representing these spatial and temporal data, and the majority of this research has evolved from the pedometrics community (see later section). For spatial and sparse data, the challenges for attribute mapping are now generally well understood within the PA community, although generally poorly disseminated in the wider agricultural community. The mapping

Fig. 3 The Precision Agriculture cycle indicating spatial referencing as the enabling, central technology that drives the other parts of the cycle. This follows a typical quality control cycle of observation, analysis, decision and action, which repeats to improve performance incrementally. Reproduced with permission from the Precision Agriculture Laboratory, University of Sydney.

of temporal effects remains a challenge for PA at present. Displaying either raw or processed agri-data is generally easy in agriculture with the advances in Geographical Information Systems (GIS) and computer graphics in other domains.

Decision Support Systems: The success (or failure) of PA or any management strategy depends on the quality of decisions that are generated through the strategy. This is the most important and the hardest part of the PA cycle to complete. If the wrong decision is generated, then growers will not adopt PA (Adrian et al., 2005). Agri-decisions can generally be labelled as embedded or information-intensive (Miller et al., 2018). Embedded decisions tend to be universal and do not require the grower to pass their knowledge to the process. Information-intensive decisions are the opposite and will be very dependent on grower-specific conditions. Autosteer using GNSS is an example of an embedded decision – the tractor drives straight in a repeatable line with many associated benefits without the grower needing to interact with the system. Variable-rate nitrogen application is an information-intensive decision. There is no ‘correct’ answer. The rate will depend on local environmental conditions, the producers production goal (e.g. animal feed vs premium wheat production), previous management, expected or forecast seasonal conditions, access to technology and advice, the producers’ level of acceptable risk, and so on. For these types of decision, decision support systems (DSSs) need to be as flexible, transparent and responsive to grower needs as possible (Lamb et al., 2008). A one-size-fits-all DSS system will not work for such decisions. The availability of flexible DSS for agriculture is very limited at the moment.

Differential Action: The differential application of production inputs at finer spatial or temporal resolutions is essentially an engineering and control problem that is being driven by the private sector. Many different, effective systems are commercially available to allow for differential production management on farms. Access to this technology is not a limitation, although cost may be prohibitive. The main constraint to the adoption of differential management is the quality of and trust in the decision(s) to be enacted, i.e. the availability of good agricultural DSSs.

Evolution of global navigation satellite systems

As noted previously, the game-changing technology for the evolution of PA has been access to satellite-based navigation systems. Collectively known as a GNSS, they are more ubiquitously referred to as GPS (Global Positioning System), which is the name of the GNSS operated by the government of the United States of America. The first GNSSs, namely the (then) USSR’s GLONASS and the USA’s GPS, arose from the space race and the cold war from the 1950s to 1980s, and the need for both military bodies to have more precise location information. The advantages of a global navigational system, and the need to avoid dependence on another government, has seen the EU and China also establish their own GNSS, Galileo and Beidou, respectively.

Although conceived for military purposes, and still used as such, the potential civilian and commercial usages of the technology were quickly identified and in the late 1980s the US government became active in promoting these uses via their GPS constellation. However, to stop the potential misuse of the technology, especially by foreign governments against the USA, the civilian access to the GPS signal, known as the Standard Positioning Service (SPS), contained a deliberate corruption in the signal, referred to as selective availability (SA). The US government retained a highly accurate, uncorrupted service, the Precise Positioning Service (PPS) for their military and for authorized users. The collapse of the USSR in the late 1990s led to a decline in the maintenance of the GLONASS system, and limited the Soviet/Russian ability to commercialize the system to the same extent as the USA, although GLONASS receivers for navigation were still available.

Unfortunately for agriculture, GNSS receivers used on farm vehicles were initially restricted to the lower quality SPS signal, and thus had potential errors of 100 m in the recorded coordinates because of the SA degradation. As PA developed in the 1990s, this was recognized as a major limitation to mapping and navigation, and led to the adoption of differential GPS (DGPS) systems in agriculture. These DGPSs monitored the SPS error in real-time against a known, fixed point, and transmitted a correction signal. There was a large diversity in the way that this differential correctional was transmitted but when received it enabled the position to be corrected to about a 1-m error. This made the geolocation suitable for many agricultural applications. The DGPS, however, was still not precise enough for autosteer systems or repeatable, control trafficking in fields. To achieve this, receivers that used another mode of correction, known real-time kinematic GPS (RTK-GPS) were developed to provide <0.05 m accuracy by analyzing the phase of the satellite signals and the information contained within the signal. The DGPS and in particular the RTK-GPS receivers were considerably more expensive than the stand-alone SPS receivers, but were necessary for agricultural uses.

By the late 1990s, it was clear that technological advances and commercial needs had developed effective solutions to the SA degradation and it was no longer a suitable deterrent for achieving sub-meter positional accuracy using the GPS constellation. Consequently, in May 2000, the SA degradation was removed from the SPS signal, enabling <1 m accuracy to be achieved with the uncorrected SPS signal. This SPS signal now enables accurate navigation with smartphones and is ubiquitous in our daily lives. This reduced the cost for GPS and GNSS receivers in agriculture for most applications, although for auto-steer and guidance systems, higher quality and more expensive receivers (e.g. RTK approaches) are currently still necessary for <0.1 m accuracy. To overcome this limitation, innovation continues and research into Precise Point Positioning (PPP) is ongoing to enable stand-alone GNSS receivers to resolve GNSS system errors in near real-time and to achieve high quality positioning (<0.1 m) with the SPS signal. This is being enabled by an increase in the amount of information and signals being generated by modern GNSS satellites and the access to and diversity between different constellations, i.e. the rise of multi-GNSS receivers.

Sensing systems for precision agriculture

Precision agriculture is not defined by data, it is defined by being able to make agricultural decisions at finer spatial and temporal resolutions than by current, conventional practices. However, it is certainly true that PA has been greatly enhanced by the emergence of a wide variety of sensing systems that provide agri-data and agri-information at increasingly finer spatial and temporal resolutions.

It is impossible in this short section on PA to define and list properly all of the sensing systems available for use with crop and livestock production. The intent here is to introduce the main types of agri-environmental sensing systems available and used for PA. For more information on soil-specific sensing systems in particular, interested readers are directed to other chapters and sections in the Encyclopedia.

What type of sensor?

Scientific principle - physical vs. chemical vs. biological sensors

Agri-systems are very diverse and the information desired or required by producers is equally diverse. For this reason, there have been a multitude of different scientific principles used to develop agri-environmental sensors. The most common approach is to use some part of the electromagnetic spectrum (EMS) that is known to react to specific physical or chemical properties of the target. This is particularly true for vegetation monitoring where, for example, reflectance from plants in the visible bands (red, green, blue; RGB) of the electromagnetic spectrum is related to chlorophyll content (chemical property) in the foliage, while reflectance in the adjacent near-infrared bands (NIR) is related to cellular structure (physical property) (Mulla, 2013). Optical sensors in the Visible–NIR region of the EMS are the most common sensors deployed in agriculture. However, many other parts of the EMS are also used to record agri-environmental data, for example reflectance in the radar region can also be used for biomass monitoring while measurements of naturally occurring gamma emissions are used to characterize soils. Essentially, if energy is transformed and reflected or emitted in a particular way from a target, then sensors that record the relevant part of the EMS can be used to collect data. The issue with sensors based on the EMS is that the reflectance or emission is a general response and not related directly to a specific property, i.e. the signal can be affected by multiple effects.

Alternatively, sensors can be constructed that directly interrogate a phenomenon of interest. For example, measurement of yield is based on physical sensors that either directly measure mass (load cells) or can infer it, such as impact plates that use the 'Force = mass x acceleration' principle. Similarly, when the property of interest is a chemical property, such as the soil pH, sensors based on chemical principles can be developed and deployed, provided that the sensing process is robust enough to be applied in field situations.

In addition to physical and chemical properties, sensors based on biological principles can also be deployed, although their development and commercialization is rare. For example, a sensor that measures the local microbial activity in soils has been proposed but not yet commercialized. Similarly, lateral flow devices can be used to test locally for specific chemical or biological compounds, such as enzymes or DNA sequences that are indicative of pests, weeds or diseases. In general, options for chemical and biological sensing exist, but the translation of the process into a relatively cheap and mobile platform limits their wider deployment in PA.

Proximal vs remote-sensing

In agriculture, sensors can be deployed near the target (proximally) or at a distance from the target (remotely). In many cases, especially with sensors based on the EMS, the same type of sensor can be applied at different distances or on different platforms. For example, multi-spectral optical sensing can be performed from satellite, aerial including UAVs, and terrestrial platforms. Regardless of the platform, these sensors will provide information on reflectance from the target, e.g. a crop, in the visible and NIR regions of the EMS. The difference between the sensors is in their footprint (area sensed) and temporal repeatability, i.e. their revisit time. The timing of information from satellites depends on the configuration of the constellation, while terrestrial systems can be operated when and where the operator chooses to.

Proximal sensors may be invasive or non-invasive in nature. Invasive sensors physically interact (are in contact) with the target. Soil electrical resistivity (ER) sensors are an example of an invasive, proximal sensing system that requires direct soil contact for the sensor to operate. In contrast, electro-magnetic induction (EMI) sensors for apparent soil electrical conductivity (EC_a) are an example of a proximal, non-invasive sensor, where the sensor is mounted above the soil surface. Many non-invasive sensors can also be deployed as remote sensors.

Active vs passive sensors

Agri-sensors may also be defined according to whether they are active or passive in nature. An active sensor emits some form of signal and measures the reflectance from or reaction of the target to the emission. Passive sensors, in contrast, only measure the target under ambient conditions. For example, passive optical multispectral sensors interrogate the reflectance of sunlight from the target. They cannot be deployed at night or under low-light conditions. In contrast, an active optical multispectral sensor will have its own light source and measure the reflectance of the emitted light from the target. These sensors do not depend on the presence of ambient light and can be operated at any time, including at night. Soil EMI or ER sensors are both active sensors, while a gamma-radiometer is a passive soil sensor that measures the emission of gamma radiation from the natural breakdown of isotopes within a soil.

A sensor of a property or a response?

Finally, in an agricultural context, it is important to understand if the sensor is directly measuring a soil (or agronomic) property or a response. For many agri-environmental situations, information is needed on a specific soil (or crop) property for decision-making. Some sensors measure (or estimate) a specific property but many, including the most common sensors, only measure a more general response, which is linked to a property of interest. For example, soil EMI or ER sensors are widely used to map soil variation, with larger EC_a values typically attributed to stronger textured soils (more clay). However, these sensors directly measure the response of the soil to an electro-magnetic impetus, which is only influenced by textural properties. Soil EC_a is not a direct estimate or measurement of soil particle-size distribution and is affected by other soil properties, including moisture content, temperature, soil pH etc. Consequently, the EC_a response requires calibration that will be specific locally to convert the EC_a response to a soil property (e.g. clay percentage). The EC_a cannot be assimilated directly into models or decision support systems as a surrogate for texture without such a calibration. Some sensors, e.g. on-the-go soil pH sensors do measure a soil property directly (pH in this case) and thus the sensor response could be used directly in models requiring soil pH information. When considering the use of sensor data, a clear understanding of whether the sensor measures the property of interest or is a surrogate or a more general response is important to understand the limits to the use of the sensor data in decision-making.

What type of data or information?

Soil

On-the-go, high-spatial resolution proximal soil sensing is dominated by systems that measure the apparent soil electrical conductivity (EC_a) (Corwin and Lesch, 2005). This can be achieved by either electro-magnetic induction (EMI) sensors or electrical resistivity (ER) sensors. Several commercially and widely used EMI and ER systems exist worldwide (some examples are shown in Fig. 4). An EMI sensor emits a primary electromagnetic field, which generates a secondary field within the soil system, and the interactions between the two can be used to generate an estimate of EC_a . For ER systems, dipoles are inserted into the soil (usually as a rolling disk) and a current is introduced. The drop in voltage between dipoles at fixed differences is a measure of soil resistivity, the inverse of conductivity (EC_a). By changing the distance between the emitting dipoles in either system, changes in the depth of exploration (DoE) can be made. Therefore, both systems have the potential to measure at multiple and various depths. For PA, this is particularly useful as the EC_a response of the topsoil and subsoil can be measured by fairly compact, mobile, manageable sensing systems. The advantage of the EMI sensor is that it is contact free, thus it can be elevated above the soil surface to change the DoE or to change the mounting platform, i.e. aerial systems to measure inaccessible areas or boat-mounted systems to sense along waterways are possible. The ER systems are limited by the need for good soil contact for the current to pass into the soil; this creates issues particularly in dry, hard and or stony soils. In contrast, EMI systems have problems in soils with very poor conductivity (i.e. very sandy conditions). As mentioned previously, EC_a is a soil response that is strongly influenced by texture and moisture content, but is also affected by soil temperature, pH, CEC (cation exchange capacity) etc. Mapping texture is very important for PA, to understand where production will differ.

Fig. 4 Images of some commonly used, commercially available apparent soil electrical conductivity (EC_a) sensors. (A) the Veris 3100 (Veris Technologies, Salina, KS, USA), which is a proximal, invasive sensor based on electrical resistivity; (B) the Geonics EMS8DD Mk2 sensor, which is a proximal, non-invasive electromagnetic induction (EMI) sensor (Geonics Ltd., Mississauga, ON, Canada) and (C) the DualEM-1s, which is also a non-invasive, proximal EMI sensor (DualEM Inc., Milton, ON, Canada). Note: Other, similar sensing systems are also available.

In addition to EC_a sensors, the other two available on-the-go proximal sensors are gamma-radiometers (GR) and ground penetrating radar (GPR). Gamma-radiometers are useful for mapping soil types, on the assumption that different soil types have a different chemical signature that generates a different profile of gamma emissions from the soil (Wong and Harper, 1999). In many cases this is related to the local pedology and parent material of the soil. The GR contains a crystal that collects and attenuates the gamma emissions so that they can be recorded as an energy spectrum. This spectrum is then processed to identify the total count of emissions and emissions linked to key isotopes (K (potassium), Th (thorium) and U (uranium)). Patterns in EMI and GR may be similar if the variation in soil texture aligns with the pedology, however, they often diverge as EC_a is affected by multiple soil properties, including texture, but is less affected by the chemical composition of the soil (its parent materials) (Castrignanò et al., 2012). Furthermore, different pedological processes and parent materials can generate a similar texture profile. The GPR systems measure the vertical reflectance of radar waves into the soil and can distinguish abrupt changes in density within the profile (Lombardi et al., 2022). These sensors are particularly useful in situations where the depth of a contrasting horizon is needed, for example the depth of a peat soil over the in-situ soil profile, or for mapping artifacts, such as tile drainage lines. The use of GPR to date has been limited in PA, both in research and commercially. Recent advantages in signal processing are showing more potential uses, especially for mapping subsoil constraints such as plow pans and stone lines. The ability to map the potential rooting depth, which can have a major effect on plant available water and crop yield, is the key advantage of GPR systems over other soil sensors.

Soil pH and soil organic matter are two key soil properties of interest to agricultural production. Neither of these has a strong effect on the previously listed sensors (EMI, GR or GPR) and there has been considerable research effort put into the development of dedicated soil pH and carbon (C) or organic matter (OM) sensors. Soil pH mapping has been successfully done with ISFETs (ion selective field effect transistors) or with electrodes (similar to pH measurements in a laboratory) (Archbold et al., 2023), and this latter approach has been commercialized. Soil C is typically estimated by a near-infrared (NIR) spectrometer, with the spectral response calibrated to the soil C or OM content (Kuang and Mouazen, 2013). This is typically mounted on a plow-like tine that enters the soil at a fixed depth and scans the soil as the 'tine' is pulled through the soil (Hodge and Sudduth, 2012). Again, this sensor has been commercialized. Although commercial soil pH and C sensors are available, and have been since the early 2000s, uptake is still limited. This is mainly due to reliability of the sensors, for example the soil pH sensor does not work well in hard or stony soil types, or they provide limited information, for example both sensors give only soil pH or C at one fixed depth (which is usually in the topsoil) and subsoil information, particularly for pH is unavailable. Furthermore, for pH mapping, the real agronomic decision (lime requirement) depends on the soil pH and the buffering capacity of the soil, and this latter information is usually unavailable from on-the-go soil pH sensors. These two sensors highlight some of the limitations for soil mapping in PA, namely that the on-the-go sensor does not always provide the desired agronomic information or at the right resolution or depth for production decisions.

From a remote-sensing perspective, options are available to measure and map soil from aerial and satellite systems. This has been applied predominantly to topsoil mapping using multispectral or hyperspectral sensors over bare soil (Mulla, 2013). Under bare soil conditions, good relations with soil type, texture and carbon content can be generated with local calibration and ground-truthing. This is effectively relating soil color to soil properties. Several commercial companies sell soil information based on bare soil imagery, however the ability to do this changes as crop and soil management changes. The adoption of direct-drilling into no-till and even min-till systems will limit this technology as it cannot work if the soil is not tilled. More recently, with the rise in availability of satellite-based, active radar systems and in the academic knowledge of how to process and interpret radar imagery, there is an increasing interest in mapping soil moisture from space. While this technology is not yet mature, the need for such information is likely to encourage rapid development in this area. Finally, as mentioned above, EMI and GR are passive, non-contact systems and can be mounted on aerial systems to survey large areas and in the case of EMI, to large depths (> 5 m).

In addition to on-the-go soil sensors for mapping, PA also relies on networks of static, usually low-spatial resolution soil sensors. This is particularly the case for soil moisture sensing using capacitance, time-domain reflectometry or, less commonly now, neutron-probe sensors. For PA, it is usual to use the high-resolution soil information discussed above (often together with crop data) to stratify static soil sensors into commercial production systems. This ensures that information is gathered at points relevant to production, e.g. areas of high or low productivity.

Crop

For PA, there are many sensors aimed at monitoring and measuring crop attributes, predominantly vigor or biomass or yield. The most common sensors applied to crops are optical multi-spectral sensors. These measure how visible and near infrared (NIR) light reflects from the canopy. Differences in reflectance indicate different levels of vigor. As indicated previously, these multi-spectral sensors generate a generic response of relatively higher or lower vigor. The reason for the differences in vigor (over space or over time) cannot be determined directly from a multispectral imaging system. It may be related to disease or to environmental conditions, and in nearly all cases it is likely that there are multifactorial environmental and management effects that contribute to the relative vigor of a crop at a given time in a given space.

If the spectral resolution of the sensors is increased, from a multi- to a hyper-spectral system, then there is considerably more information in the spectral signal and it becomes possible to extract some specific information pertaining to crop health and crop nutrition (Mulla, 2013). For example, hyperspectral information can be used to determine the local presence of specific crop diseases on the foliage that affect overall crop vigor. Likewise, nutrition deficiencies in the leaves may be expressed differently in hyperspectral imaging. Hyperspectral imaging systems are becoming increasingly more available (lower cost, more robust) for field use and are expected to become more common on-farm in the coming decade.

There has been a sharp rise in the use of normal (RGB) imagery, coupled with machine-learning techniques, for site-specific crop management. Imagery from everyday camera systems, including mobile phone cameras, can be processed with trained algorithms to generate useful agronomic information, and the potential applications are many and varied. A particular focus has been put on local estimation of crops with this approach to count tiller heads automatically in cereal systems (e.g.; Fernandez-Gallego et al., 2020), bunches or individual berries in grapes (*Vitis* sp.) (Nuske et al., 2014), individual fruit in arboriculture or even potato (*Solanum tuberosum* L.) tubers if plants are dug up mid-season. In addition to counts, these systems can also estimate size ranges (quality distributions) if the imagery is properly corrected (Fig. 5). Identification of defects or diseases on the crop or the foliage or just estimates of leaf area is also possible in real-time in the field (e.g. Richey et al., 2020). The technology is not yet perfect and some issues remain, particularly with errors associated with the occlusion of the crop by the foliage and a need for better standardization and or harmonization of image collection. Despite this, better estimation and site-specific estimates of yield will transform crop estimation and management. This will be especially important in high-value crops and for crops where robots will be more commonly employed.

The other dominant crop sensors deployed in PA are yield sensors. These can be either harvest-mounted sensors that audit production as it is harvested or some form of imaging system that counts or records yield near harvest (i.e. a near-harvest crop estimate as described above). On-harvester yield sensors are one of the foundation technologies in PA and particularly in arable cropping (example in Fig. 6). It was the collection of these data and the observed large spatial variation in yield that encouraged much of the initial interest in PA. Nowadays, yield sensing systems exist for most machine-harvestable crops. Tracking systems also exist for hand-harvested crops, but these have much less market penetration and acceptance than on-harvester yield monitors.

Fig. 5 Example of a next generation in-season grape sensor based on image analysis and machine-learning algorithms. The sensor (A) images the grapes on-the-go as it is driven through the vineyard. Image analysis processes are then used to count the visible berries, estimate the average berry size and to determine berry color (B). This can be used mid-season to manage crop load in vineyards, or near harvest to determine if grapes are ready for harvest (meet the market demands for quality). Images courtesy of the Efficient Vineyard project (Dr Terence Bates, Cornell) and the Carnegie Mellon Robotics group.

Fig. 6 Examples of yield (i) and grain protein content (ii) in a wheat field from a farm in north-west New South Wales, Australia. Both maps show the raw data and clearly show the inverse spatial relationship between yield and protein in this field in this year (high yield - low protein and vice versa). The squares in the yield map show 1-ha areas of consistently low yield (a), consistently high yield (b) and variable yield (c), highlighting the differences that can be found in 1-ha areas with regard to the amount and variation in yield. Reproduced with permission from Whelan BW and Taylor JA (2013) *Precision Agriculture for Grain Production Systems*. CSIRO Publishing, Dickson, ACT, Australia.

Many different types of yield sensors are available but they tend to be based on a few key principles. These are (i) directly weighing the crop using load cells under a conveyor belt or collection bin, (ii) measuring the force exerted by the crop on an impact plate (at a known acceleration) so that mass can be calculated, or (iii) counts associated with the disruption in a light beam(s) as the crop passes through a pipe or tube. All three approaches have advantages and disadvantages depending on the manner of harvest and type of crop, however, if properly calibrated and used, they will all generate useful data. For many harvesters, especially combine harvesters, yield monitors are standard nowadays.

Quality sensors also exist for some crops, notably for protein in cereal crops (Fig. 6), but are absent in many others, particularly for root vegetables. Grain protein sensors use NIR spectroscopy in real-time to assess grain quality on harvesters, but this form of sensing is less common than for yield (quantity) sensing (Long and McCallum, 2020).

Animal

Precision agriculture is not just limited to crops, but can be applied equally to livestock industries. Since animal production depends on feed production, many of the soil and crop technologies discussed above can also be deployed in forage and fodder production systems. While the potential exists, the commercial (and research) development has been slower. Sensing in pastures is complicated by species diversity and the temporal evolution in the dominant species over the year (in contrast to monoculture situations in arable and horticultural crops). This makes decision-making more complicated and, even with the same technologies, different decision processes are needed. The perceived value in these has had limited investment to date (relative to arable crops). There has been very little pasture-specific sensor development to support precision pasture management, except that of a yield sensor for forage harvesters. Some existing NIR sensors have been commercialized and can be calibrated to provide real-time quality (protein, sugars, fiber, etc.) information during silage or hay operations.

In addition to pasture sensing, many different types of animal-specific sensors are available to provide information on animal movements, animal feeding habits, rate of animal growth and general behavioral or well-being. The use and availability of these is increasing rapidly.

Meteorological

Agricultural production, except for controlled atmosphere systems like growth chambers and sealed greenhouses, depends on the weather. Accurate observations and forecasts of weather conditions are very important for good agriculture management. First, such information is critical to the use of many different types of models to support decision-making, e.g. epidemiological models of pest life cycles and optimal times for pest control interventions or modeling crop phenological development for the optimal timing of plant nutrition. Second, it is important to have a correct (and up to date) understanding of water supply (precipitation and evapotranspiration changes) relative to the needs of the crop for yield potential and evolving in-season crop management to meet this potential. Last, correct short-term forecasts can be critical for achieving timely operations, especially leading to extreme or large weather events.

On-farm meteorological data can be obtained from fixed weather stations, and these are often commonplace on large farms. However, on large farms there can be a considerable difference between the weather in different fields, if not in the same field. This is especially true for precipitation events that can be very localized. Therefore, a fixed weather station near the farmhouse may not be

completely relevant to the entire production system and will be unable to measure meso-climatic variations across a farm. Areas prone to frost, such as hollows, or with a different aspect, could experience very different local weather conditions. Therefore, care is needed when extrapolating some weather information across farms.

A modern alternative is to use virtual weather stations based on large-scale weather models that can provide 'local' (typically 1 km²) predictions of hourly or daily weather conditions. These observations are predictions, but very short-term (typically 1 h predictions) that have been up-dated and corrected based on recent observations at a network of connected weather stations. For some key properties, particularly temperature, they are usually very accurate and are suitable for use in many agriculture models (Launspach et al., 2017). Local predictions of precipitation can still be problematic. These virtual weather stations do provide growers with an ability to obtain weather data from different meso-climates across their production systems and to have more accurate field-specific information (compared to a single, central fixed weather station).

The role of interpolation, pedometrics and digital soil mapping in precision agriculture

As outlined in the introduction to this chapter, PA has developed from the idea of '*farming by the soil*', and was informed by an evolving understanding in agriculture that soils are variable in space (and time) and that this variation can be mapped and used to make better, spatially-variable agronomic decisions. This was predicated on the ability to observe variation (i.e. the existence of new sensors) and to deploy differential (variable-rate) management in fields (i.e. developing variable-rate machinery capabilities). In addition to these technical capabilities, there was also a need for methodologies to analyze and process properly the new spatial data structures that were available to agronomists. If these data were not correctly transformed into information layers, then effective agronomic decision-making is not possible. From the late 1980s to the mid-late 1990s, the academic and industry knowledge base to process these data lay predominantly in the soil science sector.

The knowledge that soil is a variable continuum in both time (generally long periods) and space (generally short distances) has long been understood, from the seminal work of Vasily Dokuchaev in the late 1800s, through to the formalization of soil forming factors in the mid 1900s by Hans Jenny and others, leading to modern day digital soil mapping methods (McBratney et al., 2003). It is unsurprising that the spatial analysis of soil data has been strongly advocated in the soil science and geological communities. Such spatial analyses are generally referred to as geostatistical analyses. Geostatistics relates to the application of mathematics to spatial issues. In general, this is either to describe the amount of spatial variation observed in a data set (Leroux and Tisseyre, 2019) or to interpolate spatial data by predicting at places where observations have not or could not be made. Geostatistics can be used to generate maps of soil types or properties, as well as maps of production attributes (e.g. yield). Correct use of geostatistics in this manner transforms raw data into visual maps that help growers and agronomists to understand the amount and spatial distribution of the soil and crop variation on-farm (Fig. 7).

The use of mathematics and statistics in soil science has a specific term, 'pedometrics.' It is important to note that pedometrics relates to any use of mathematics or statistics in soil science, not just to spatial analyses. However, a large part of the pedometrics community, historically and nowadays, are invested in geostatistical questions. This derives from a need to survey and to map soil for many different purposes (agriculture, hydrology, civil engineering projects, environmental habitats etc.). Initially, soil surveys and soil maps were typically done at quite broad scales as it was cost-prohibitive in most cases to collect spatially dense (high-resolution) soil samples manually. However, as sensor and information technologies have evolved over the past 40 years, the scale of mapping and the type of mapping has also evolved in response to access to high-resolution spatial soil data. Soil mapping is now done almost exclusively in digital form, termed digital soil mapping (DSM), using predominantly quantitative analytical

Fig. 7 The way that maps are produced for PA has been heavily influenced by developments in pedometrics and digital soil mapping. This example shows some raw data (A), which is then overlain by a prediction grid (B), and onto which values are interpolated from the raw data (C) to form a smoothed map (D). The interpolation process filters errors in the data and smooths the patterns of variation to make them visually more interpretable by agronomists and growers.

approaches applied to high-resolution data sets. This has replaced subjective, traditional soil survey and mapping techniques that often relied on expert knowledge and were informed by limited numbers of soil observations.

Pedometrics predates PA. Before the development of Earth observation satellite systems (1970s), spatial crop information was very limited and there was little knowledge or application of geostatistics to crop sciences before the 1990s. Yield monitors and satellite imagery changed this, and resulted in a need to rapidly develop the capacity for spatial crop data analysis in agriculture. These spatial yield and biomass data were complemented by high-resolution soil data and soil mapping, and it was a natural step for the geostatistical expertise applied to soil data to be shared and transferred to crop data. The result was that many leading pedometricians in the 1990s also became leading advocates and researchers in PA, notably Margaret Oliver (Reading, UK) and Alex McBratney (Sydney, Australia). During this period, it was typical for major conferences to have plenary talks from pedometricians and there were often multiple sessions dedicated to the issue of high-resolution soil measurements and mapping for PA. Soil scientists made up a large part of the original academic PA community.

As PA developed (late 1990s and early 2000s), the demand from the cropping community for better and higher resolution soil information further encouraged developments and innovations in DSM. Effectively, it changed the target scale for DSM from hundreds of meters to tens of meters. This was of great benefit for the DSM community and also exposed DSM to many different circumstances where high-resolution soil information is needed. The result was a rapid increase in research and capacity in pedometrics and DSM, and the creation of a sustainable, stand-alone academic community. Consequently, the direct role of the pedometrics community in PA has diminished over the past decade, although interactions and shared research needs persist. The mathematical and statistical knowledge applied to PA from 'traditional' geostatistics in soil science is now being replaced by machine-learning and artificial intelligence (AI). While this has brought more computer scientists into the PA community, pedometrics has also evolved to provide knowledge to PA domains, particularly through DSM applications.

Evolving, or previously under-developed areas where PA still needs considerable input from soil scientists and pedometricians are improved sensing systems of specific soil properties, especially those associated with plant nutrition and plant available water. For several soil properties, particularly those associated with soil chemistry and soil water, this information is needed both temporally and spatially. Nitrogen and water fluxes can occur quickly during a season. This is not true for all properties because physical properties such as soil texture evolve on time scales that are irrelevant for agriculture. Furthermore, better spatial information in the vertical (depth or *z*) direction is also needed. To date, spatial variation has primarily been addressed in the *x* and *y* dimensions.

Decision-making and management units in precision agriculture

Decisions in agriculture rely on the quality of data (and information) gathered, are affected by the economic and production goals of the system (farmer), are required for a spatially and temporally varying biological system, and depend on previous and future management decisions. In addition, the majority of agriculture exists within an open biological environment. When production interacts and reacts with variable environmental and biological conditions, production becomes temporally and spatially variable. In short, agri-decisions are made in an imprecise system with few situations where there is an absolute and correct decision. From a PA context, the amount and nature of variation in a production system is a key determinant of the direction and opportunity for making decisions, determining the (absolute) quality of those decisions and imposing differential management. Optimizing spatial decisions-making and demonstrating improved efficiencies is the biggest challenge to the further development, acceptance and translation of PA.

High-resolution spatial data sets are still relatively new in agriculture and the way that the data and information are presented is still relatively novel to many producers and service providers in agriculture. Interpreting maps of production attributes is not always intuitive. Individually, single biomass images, yield maps or soil maps are relatively easy for producers and agronomists to interpret and to superimpose their own knowledge on to. This is particularly true when there are clear management and/or environmental effects in the data or information, as can be seen in some of the yield maps in Fig. 1. As more layers of data and information become available for a field, the ability to process the additional data or information diminishes, i.e. interpreting and reacting to the time-series in Fig. 1 is more complicated than reacting to the pattern in any given individual year map. It becomes even more complicated if some of the raw data are poorly presented or poorly mapped.

If PA is about better decision making, then it is paramount that the way that data are presented, transformed into information layers and how they are fused into a decision process is done correctly. The more confusion that is generated at the initial stages, the harder it is to arrive at a good decision at the end. Approaches to filtering, mapping and integrating data have been key areas of research from the inception of PA (Taylor et al., 2007). Without these basic building blocks, making decisions and therefore PA adoption and translation are not possible.

Filtering and mapping approaches continue to be updated, but the transformation of raw data into information layers is relatively well understood by academic and industry stakeholders. How these data are then compressed, fused or simplified remains an issue for the industry. Methods, and well-accepted approaches exist, however on-going evolution in the amount and type of data available is constantly challenging the way that these data can be integrated and interpreted (Lyle et al., 2014). Data fusion and the transfer of relevant information into decision systems remains a key area of development for PA (Guillaume et al., 2020). The more effective such methods are, the better the resulting decisions should be.

With improvement in sensing, algorithms, decision-making and operational capabilities, the industry will become closer to real site-specific (i.e., plant or even leaf-specific) management (Fig. 2). In the interim, however, it has been widely recognized that some intermediate resolution of management is needed (Khosla et al., 2002). This is generally referred to as the management zone or management class concept. The original term proposed was ‘management units’ (Lark and Stafford, 1997); however, the term ‘management zones’ is more commonly used in PA to describe delineating a field into smaller subfield areas for differential management operations. The delineation of management units by classification or segmentation algorithms has proved to be very effective for data fusion with different agri-data sets. The most common method used has been the *k*-means classification algorithm or a variant thereof (e.g. Fridgen et al., 2004; Taylor et al., 2007). This requires data to be co-located (either sensed or measured at the same place, and or interpolated to fixed locations) which enables *k*-means classification to effectively partition multiple datasets into zones where the input data sets exhibit a similar response. The agronomic and environmental response within a delineated zone can then be interpreted with local agronomic knowledge to devise zone-specific management plans. The advantage here is that existing, local knowledge can be easily brought into the decision-making, albeit at the end of the data fusion process.

Management units (MUs) play a key role in getting producers involved in PA. When done correctly, the producers can see how the various, often complex production layers are compressed into a single, usable map that can be interpreted with their existing local knowledge of crop and soil responses (Fig. 8). Individual MUs can be treated as virtual, fenceless fields (Taylor et al., 2007). Decisions follow a field-scale process, i.e. the general agronomy process of the grower or agronomist remains unchanged, but is applied at a smaller scale (i.e. the MU instead of field scale). This achieves a higher level of spatial management while keeping the producer in a familiar decision space. If poorly constructed, MUs will be uninterpretable, the producer will be disillusioned with PA and the default uniform field management will continue to be used. As a result, a large part of PA research has been directed at issues around generating correct MUs (Betzek et al., 2018). While the majority of the work to date has focused on arable cropping systems, tools developed for MU delineation are as relevant to perennial horticultural systems as they are to arable cropping systems.

The delineation of MUs by classification was a big step forward in multi-layer data fusion. However, the current use of MUs tends toward static patterns and they are applied as a ‘one size fits all’ approach. Fixed zones, with fixed boundaries, are used for all potential variable-rate applications within a field – for example planting, chemical inputs and fertilizer. This is (was) sensible with only limited information layers available. With more information, particularly in-season temporal information, becoming increasingly available for both crop and soil properties, there is a new opportunity to tailor MUs to specific operations and times in the season, i.e. MUs should be dynamic in space and time (Fig. 9). For example, the controlling factors of variable plant establishment will probably differ from those of variable crop development in any given field. In such cases, MUs for variable-rate seeding and fertilizer application should differ. However, it is only recently that data and information availability, linked with improved connectivity, has reached a level where the potential of dynamic MUs is a reality.

The potential for dynamic MUs, generates a new paradigm for essentially the same set of questions and challenges. How are the right data chosen in an automated way for these dynamic MUs? Which method of data fusion should be used to generate MUs that evolve with decisions and or time? Currently, with fixed, static MUs, these are delineated by an expert in consultation with the producer. This ensures a rigorous selection of input data and a standardized method of delineation. A shift to dynamic MUs will make this approach economically unsustainable. Service suppliers will be unable to provide the level of personal contact needed to be altering MUs constantly with evolving seasonal conditions and for disparate management operations. It will be the producer and or an automated system created by AI and machine-learning approaches that is likely to generate these dynamic MUs in the future. The current (and future) expert knowledge of both the agronomist and producer in selecting the relevant data for specific operations, and the method of MU delineation needs to be captured within an autonomous (self-learning) model to allow producers to derive MUs with confidence by themselves (Taylor et al., 2021).

This is not an easy objective. This shifts MU delineation from an information intensive system to an embedded knowledge system. More robust and repeatable data fusion methods are needed to replace the current use of *k*-means classification (and its derivatives). Ideally, these multivariate data fusion techniques should operate directly on the raw data and include filtering and pre-processing steps. Machine-learning techniques, particularly techniques that enable soft-computing solutions, are likely to be at the forefront of this approach to MU delineation (Fig. 9).

Precision vs. digital agriculture

The increasing level of ‘connectivity’ on farms and the need for on-going, and likely increased, interactions with computer science is a reality for modern agriculture. The digital revolution is affecting all aspects of modern life and agriculture is no exception. Digital agriculture (DA) will precipitate some disruptive changes in the food production and supply chains in the near future. It is a challenge for PA researchers, and the users of PA, to understand and utilize digital agriculture innovations to improve spatio-temporal crop (and animal) management (Bellon Maurel et al., 2022).

Precision and digital agriculture are connected, and often the latter is described in a similar way to PA. However, these are different concepts. Precision agriculture is now well-defined and concerns better (higher resolution) decision-making. Digital agriculture is still new, but it relates first to the collection and the connectivity of digital data structures. It should implicitly feed data and information into PA systems to improve them (Wolfert et al., 2017). However, on its own, DA is not a holistic decision support system. It is not concerned, for example, with non-digital data that could influence farm management. Its decision support derives directly from information and communication technologies. Digital agriculture also has a much larger scope than PA. It is

Fig. 8 A visual illustration of the general process to transform raw irregular crop and environmental data into single layer maps and the subsequent fusion of these layers into a potential management unit (MU) map (in this case using *k*-means classification). Different MUs have different yield responses. The MUs were used to target soil sampling (3 samples per MU) to explain the different yield responses. Adapted from an image first published in CSA News, which is an industry magazine that supports research published within ASA, CSSA and SSSA journals.

equally concerned with non-spatial and non-temporal data structures. This is exemplified by the fact that PA is farm and production-centric while DA is a farm to fork concept. Digital technologies in the supply chain will be a large part of the DA revolution, and will have a major role to play in evolving food security and human health issues, but these solutions may not necessarily be relevant to on-farm production management.

Finally, it is important to contextualize the role of robots and unmanned aerial vehicles (or systems) (UAV or UAS) within PA. Robots or UAVs by themselves are not PA. They are platforms from which information can be gathered or from which a decision can be implemented. Essentially, they are the next iteration in agri-machinery and are replacing existing farm machinery for certain

Fig. 9 A schematic diagram of how a change from fixed to dynamic decision zoning could operate. The process starts by (A) specifying the decision first, (B) then selecting data layers relevant to the decision (from all available layers), (C) before using a dedicated data-fusion tool that includes grower knowledge and (D) is 'zoned' only on the output (decision) from the decision support system. Adapted from Guillaume S, Bates TR, Lablee J-L, Betts T, and Taylor JA (2020) Combining spatial data layers using fuzzy inference systems: Application to an agronomic case study. In Proceedings of the 6th International Conference on Geographical Information Systems Theory, Applications and Management (GISTAM 2020), 62–71, with permission.

tasks. They are and will continue to become an important part of modern and future agriculture. However, a robot could be used to implement a uniform, flat management strategy, for example for seeding a crop, as a straight swap for a tractor-based approach. This is not PA. It becomes PA if the robot enables better decision-making at a finer spatio-temporal scale than is the norm. Platforms that host sensors or enable variable-rate management are enablers of PA. Robots and UAVs are the next generation of platforms. The PA component comes from the evolving management strategies that will use the data or information collected from these new platforms that can potentially be implemented via these platforms. Autonomous robots, in particular, have a great potential to change the scale of data collection and decision-making in agricultural fields if the analyses, decisions and actions can be effectively linked 'on-board.'

Concluding comments

Precision agriculture started with the intent to 'farm to the soil,' with the recognition that soil is a spatially variable continuum and that its impacts on production are also spatially variable. This continues to be the building block on which site-specific crop management and precision pasture management have developed. To this end, soil science will always be fundamental to PA. However, as growers can understand and manage their soil variability better for their production goals to negate these effects on production variability, then other factors and interactions become more significant and have noticeable effects on production. This is the situation that PA in developed agricultural countries now finds itself. Consequently, the PA academic community has shifted from a soil science base to a computer science base over the past 10 years, particularly at the International and European PA conferences. However, in regions where PA is less developed, especially in African agriculture, the PA community and its objectives remain more strongly aligned with soil science and managing soil variability. The resurgence of soil science needs for small-holder agriculture has been a key theme of the first two African PA conferences in the 2020s.

Pedometrics and digital soil mapping have played a crucial role in the evolution of PA over the past 30 years. The continued need for more and better soil information and at a lower cost will ensure that it continues to be a part of the next evolution in PA.

Abstract

Pedodiversity is a neologism of soil diversity concerning to the analysis of the number of soil classes or pedotaxa using mathematical procedures. However, the same tools are shown to be useful for other purposes such as the analysis of the structure of pedological hierarchical taxonomic systems and the standards for soil surveys and maps. Pedodiversity tools are described including their relations with other mathematical approaches, including: nested subset analysis, species–range size relationships, fractals and multifractals and complex systems. One of the most relevant findings obtained in pedodiversity analysis is that the patterns/regularities are the same for pedological and ecological entities, among others.

Key points

- Why should pedodiversity be analyzed?
- What are the mathematical tools applied to diversity studies?
- What patterns and regularities are detected in studies on pedodiversity?
- Comparison between the patterns of biodiversity, pedodiversity and geodiversity.
- Applications of geodiversity studies in other fields of knowledge.
- What is the role of the human mind in the patterns and regularities detected?

Introduction

Traditionally, soil has been defined from the soil forming factors (parent material, climate, biota, physiography, time and human intervention). The evolution of life on Earth has created the soil and it is impossible to imagine our planet without this natural resource, since it is the product of the interaction between the geosphere, biosphere, atmosphere, hydrosphere and cryosphere. Soil has been the driving force of plant diversity and the origin of new species. Likewise, the soil is the habitat for soil organisms and is at the interface of above- and below-ground biodiversities. Therefore, knowledge of the diversity and variety of the world's soils (pedodiversity) is vital for maintaining the biosphere, guaranteeing food security, and protecting the climate system itself.

Currently, the community of pedometricians recognizes pedodiversity analyzes as an independent line of research requiring the attention of experts from various scientific disciplines (Wadoux et al., 2021). The first attempt to analyze pedodiversity quantitatively was carried out by the Russian pedologist Vladimir Fridland in 1976 (see Ibáñez and Bockheim, 2013 and references therein). Unfortunately, his proposal had little success within the community of soil scientists. In 1990, Ibáñez and collaborators estimated the pedodiversity of a geographic space with the tools used by biodiversity experts for more than a century. Much has since been published on pedodiversity, and this chapter summarizes both the achievements and challenges existing to date.

To estimate the diversity of a natural resource, a classification or taxonomy is required and the abundances of each class in a given geographic space. The pedologist classifies soils according to their features and properties giving rise to pedological taxonomies, i.e., soil types or pedotaxa. Soil inventories and maps show the properties of soil landscapes, their diversities or heterogeneities, and how the soil may be used for different purposes. Furthermore, the value of the tools used to study diversity go beyond what we might initially think of as useful because they can be applied in various scientific disciplines and sub-disciplines. In summary, pedodiversity analyzes the complexity and diversity of soil entities, their properties, and also how they are distributed in the landscape.

The concept of diversity

According to Huston (1994, p. 65) diversity can be defined conceptually as:

The concept of diversity has two primary components, and two unavoidable value judgments. The primary components are statistical properties that are common to any mixture of different objects, whether the objects are balls of different colors, segments of DNA that code for different proteins, species or higher taxonomic levels, or *soil types* or habitat patches on a landscape. Each of these groups of items has two fundamental properties: (1) the number of different types of objects (e.g., species, soil types) in the mixture or sample; and (2) the relative number or amount of each different type of object. The value judgments are: (1) whether the selected classes are different enough to be considered separate types of objects; and (2) whether the objects in a particular class are similar enough to be considered the same type. On these distinctions hangs the quantification of biological diversity.

We consider this to be the most comprehensive description of what diversity means, with both its advantages and disadvantages.

The scientific concept of pedodiversity

The Huston Concept of Diversity (Huston, 1994, p. 65) is valid as a first approach to the concepts of biodiversity, pedodiversity and geodiversity among many others. In all cases there is a need to define the “objects” of study precisely. In general, there are many classes of objects for all the scientific disciplines. For example, in ecology the first focus was biological species, followed by interest in the hierarchy of the “object.” The concept of biodiversity began with biological species because they were considered naively to be real entities, while other taxonomies were considered abstractions. The current terminology on biological diversity includes terms such as genetic diversity, habitat diversity, functional diversity, landscape diversity, and so on. Likewise, pedologists consider the diversity of soil types, soil horizons, soil attributes, soil biota, soil niches, etc., but also refer to functional pedodiversity. Furthermore, in pedometrics, mathematical tools are used to split the character space into classes derived by grouping the soil variables that are considered to be of interest for solving specific problems. On the other hand, geostatisticians retain continuity in geographical space to indicate spatial diversity.

Pedodiversity and its measurements

The study of pedodiversity arose because the soil cover is very complex and there is the need for an index or indices to measure it. Pedodiversity in fact embraces a range of diversities (Ibáñez et al., 1995a,b). However, the definitions mean nothing unless they are operationalized to be used in a scientifically sound way with mathematical tools.

Ibáñez and Bockheim (2013) among many others use taxonomic pedodiversity to embrace:

1. Applications of pedodiversity tools to detect soil spatial patterns, including pedodiversity–area and pedodiversity–time relations,
2. Patterns of pedological assemblages (soilscape, soil regions, etc.),
3. Pedogenetic diversity related to soil horizons in a given region,
4. Quantitative mathematical concepts and tools useful in soil geography such as quantification of soil endemisms,
5. Pedodiversity indices from the application of non-linear or complex systems, or dissipative structures in pedology such as convergent versus divergent pedogenesis,
6. Genesis of soilscape,
7. Areas selected for designing networks of natural reserves for soil preservation,

8. Other regularities in soil assemblages such as potential nesting among them, species–range size distribution, scale invariance or scale dependence of soilscape patterns,
9. Comparison of diversity patterns in space and time of different natural resources (e.g., soils, rocks, landforms, minerals, biological diversity),
10. Spatial representation of the variation in soil properties across landscapes with soil taxonomies,
11. Mathematical analysis of the structure of pedological and biological taxonomies,
12. Relations between mathematical tools of diversity and properties of free scaling laws (e.g., fractals and multifractals),
13. Use of diversity mathematical tools to analyze the structures of maps,
14. Cognitive bias in taxonomies, soil mapping and scales, as well as diversity results.

Most pedogenetic studies have mostly been concerned with the formation of the soil body over time. Jonathan Phillips (2013) and co-workers among others have analyzed this topic in depth, showing that pedodiversity tools open new perspectives on pedogenetic theory (divergent pedogenesis) from the point of view of complex or non-linear systems, challenging traditional concepts. The now popular digital soil mapping (DSM) tools offer new opportunities for pedologists with an interest in pedogenesis and pedodiversity from a spatial perspective (Fajardo and McBratney, 2018).

State of the art on the relations between pedodiversity and biodiversity and their preservation

It should be noted that the spatial and temporal patterns of the distribution of soil types in the landscape are strikingly similar to those of aboveground biodiversity such as the following macroecological patterns (see Ibáñez and Bockheim, 2013 and chapters therein): (i) species (taxa)–area relationships; (ii) local–regional richness relationships; (iii) latitudinal gradient in species richness; (iv) altitudinal gradient in species richness; (v) species–range size relationships; (vi) nestedness of species occurrence; (vii) abundance–range size distribution, and (viii) species–abundance distribution.

Several studies have shown that different soil types as well as different soil horizons have different assemblages of soil living organisms, demonstrating that they should be considered as diverse habitats. The soil microbiome appears to be self-organized, including soil aggregate habitats (e.g., Karimi et al., 2020).

It is clear that if we want to preserve biodiversity, we must also preserve pedodiversity (see Ibáñez, 2017 and references therein). For this reason, various soil scientists have proposed quantitative frameworks to create networks of soil reserves and or the inclusion of pedodiversity in other programs related to efforts to preserve nature with the aim of including a framework of pedological entities that must be preserved for their intrinsic value. These include landscape and soilscape metrics, and databases on pedotaxa in risk of extinction. The considerable degradation of the biosphere and geosphere has profoundly altered the pedosphere. Several studies have shown that in certain countries and geographical areas there has been both a loss of pedodiversity and the transformation of some pedotaxa to others (e.g., Lo Papa and Dazzi, 2013 and Bockheim and Haus, 2013 in Ibáñez and Bockheim, 2013). Human actions have transformed the pedosphere to such an extent that new anthropogenic taxa are included in modern soil taxonomies, such as the WRB–FAO Reference groups of Technosols and Anthrosols (IUSS Working Group WRB). There has been a loss of certain types of natural soil that have been replaced by others of anthropogenic origin (Zhang, 2013; in Ibáñez and Bockheim, 2013).

Ibáñez and Montanarella (2013) show that pedodiversity studies require the categorization of the different classes or types of soil. These could be universal, national or “ad hoc” classifications. Universal taxonomies allow for a comparison of the results obtained in different studies, whereas ad hoc classifications would be more useful for purpose-oriented studies. However, different soilscales might require the selection of very different variables for an adequate description of the area’s soils (e.g., permafrost versus arid land taxa). Nevertheless, each approximation has advantages and disadvantages. For instance, national taxonomies often provide better results than universal ones because their taxonomic constructs are adapted to their study area, and are therefore more precise and locally specific. However, the results cannot be compared easily with those obtained in other countries with their own national taxonomies.

The conundrum problem to reach full diversity inventories

How many biological species are found on Earth? How many mineral species are part of the Earth? How many soil types or pedotaxa are found on Earth? (and so on).

Unfortunately, no one can answer these questions in a sound scientific way. Every day new species are discovered or become extinct, every few years all taxonomic structures are changed or reorganized. Consequently, scientists must recognize that the rigorous estimation of diversities according to some premises underestimates what really exists in the world around us.

Main mathematical tools in diversity analysis

It is common in the ecological literature to distinguish between three types of diversities, which have been adopted and used in pedodiversity analysis.

- o α (Alpha) diversity richness is the number of taxa found in a particular geographical space. Usually, it is termed “richness” or “S.” If, only a sample and not the entire population can be obtained, it is necessary to distinguish between numerical richness and “object density.” In the case of a soil survey, the former would be defined as the number of different pedotaxa found in the study area. The latter would refer to the number of pedotaxa per sampling area (see Magurran, 1988).
- o β (Beta) diversity richness is the difference in taxa composition between two areas or regions. It takes into account their diversity as well as the number of distinctive species that appear in each studied area. For example: if land unit 1 has 6 taxa: a, b, c, d, e, and j (α diversity = 6) and land unit 2 has 4 taxa: a, b, k, l (α diversity = 4), to calculate the β diversity the number of overlapping species (or pedotaxa) of each α alpha diversity must be subtracted and the results summed: (6 taxa on land unit 1–2 overlapping taxa) + (4 taxa on land unit 2–2 overlapping taxa) = (6–2) + (4–2) = 4 + 2 = 6. Thus β diversity between land units 1 and 2 is 6.
- o γ (Gamma) diversity richness is a measure of the overall number of taxa or richness (the diversity) within a region or study area. It is basically the sum of all the taxa in the complete study area involved (land unit 1 + land unit 2). In this example γ would be 8.
- o Formal diversity indices are indices based on the proportional abundance of objects and are the most frequently used. They consist of two components: (i) the variety (richness); and (ii) the relative abundance (evenness or equitability) of species (Table 1). Several techniques have been proposed to measure diversity (Magurran, 1988). These are the Shannon negentropy index proposed by Shannon and Weaver in 1948 and the Brillouin index proposed by Brillouin in 1956 (Magurran, 1988).

The Shannon index is calculated by the following formula:

$$H' = - \sum_{i=1}^m p_i * \ln(p_i) \quad (1)$$

where p_i is estimated as n_i/N (n_i is the area covered by the i th pedotaxon and N is the total area under study). The index H' is usually between 1.5 and 3.5 and only rarely surpasses 4.5. The ratio of observed diversity to maximum diversity (this occurs when all elements are equally abundant) is taken as a measure of evenness “ E ” (Pielou, 1969 in Magurran 1988) (Fig. 1).

Table 1 Conversion of common indices to true diversities after Jost (2007).

Index H	Diversity in terms of H		Diversity in terms of p_i
Species Richness	$H \equiv \sum_{i=1}^S p_i^0$	H	$\sum_{i=1}^S p_i^0$
Shannon Entropy	$H \equiv \sum_{i=1}^S p_i \ln p_i$	$\exp.(H)$	$\exp \left(\sum_{i=1}^S p_i \ln p_i \ln p_i \right)$
Simpson concentration	$H \equiv \sum_{i=1}^S p_i^2$	$1/H$	$1 / \sum_{i=1}^S p_i^2$
Ginni–Simpson index	$H \equiv 1 - \sum_{i=1}^S p_i^2$	$1/(1-H)$	$1 / \sum_{i=1}^S p_i^2$
HCDT entropy	$H \equiv \left(1 - \sum_{i=1}^S p_i^q / (q-1) \right) [1 - (q-1)/H]^{1/(1-q)}$		$\left(\sum_{i=1}^S p_i^q \right)^{1/(1-q)}$
Renyi entropy	$H \equiv \left(- \ln \sum_{i=1}^S p_i^q / (q-1) \right)$	$\exp.(H)$	$\left(\sum_{i=1}^S p_i^q \right)^{1/(1-q)}$

Fig. 1 The figure represents the concepts of richness and evenness. While both boxes have the same number of objects (99) and classes (3), their distribution is different, meaning their richness values are equal ($S = 3$) but their evenness varies. In box (A) evenness has a low value because most objects are concentrated in only one class, while in box (B) evenness is 1 because all objects are equally distributed among classes.

The Brillouin index is calculated as follows:

$$HB = \frac{\ln N! - \sum \ln n_i!}{N} \quad (2)$$

where N is the total number of pedotaxa and n_i is the number of individuals belonging to the i th pedotaxa.

Minasny et al. (2010) suggested that taxonomic distance or taxonomic differences between soil classes could be used to obtain a diversity index in trying to improve the estimation of pedodiversity (also see Ibáñez and Bockheim 2013).

The above formulae are commonly applied in pedodiversity and use three types of input: (i) the number of individuals of a given pedotaxon; (ii) the proportion of the area characterized by a given soil type; and sometimes (ii) the number of diagnostic horizons identified in each sample. The first two result in taxonomic pedodiversity, while the last one constitutes a first approximation to the genetic diagnostic horizon diversity or genetic pedodiversity (see Ibáñez, 2017). Ibáñez and Effland (2011) apply these mathematical tools to each level of a given hierarchical pedological taxonomy because they consider that this procedure shows the relevance of different soil forming factors that are the major determinants of each of these hierarchical levels.

Regardless of this variety of indices, with their respective virtues and imperfections, several authors show how most of them are strongly correlated (Table 2). Similarly, different evenness indices tend to be closely correlated (see; Feoli et al., 2013 in Ibáñez and Bockheim, 2013).

Richness–area relationships

The area–species relationship (SPARs) is one of the topics most widely accepted and corroborated empirically in pedodiversity studies (see Ibáñez and Bockheim, 2013; and chapters therein). The increase in the number of taxa is represented graphically against the area sampled in a double logarithmic plot and a straight line is obtained, indicating a power law (MacArthur and Wilson, 1967, in Magurran, 1988), whose simplest mathematical formulation is the following:

$$S = C \cdot A^z \quad (3)$$

where S is the number of taxa encountered, A is the area sampled, C is an empirical constant, and z is the slope of the curve in the log–log plots. Thus, C and z are empirical constants which would vary from some taxa to others and from one locality to another. The smaller the z value, the less will be the increase in the number of taxa according to the increase in area.

The SPARs is also another way to explore, quantify and compare the complexity of abiotic landscape structures in different areas and environments. According to the *Theory of Island Biogeography* (MacArthur and Wilson, 1967 in Magurran, 1988) a seminal theoretical construct used in ecology, the dependence of S (number of different taxonomic groups) on the area A (referring in particular to islands and other analogous land fragmentations approaches such as drainage basins, bioclimatic belts, etc.) can be modeled by a power law (Fig. 2A).

The SPARs have been considered the cornerstone of the biogeography and conservation biology sciences. In view of the similarities that occur with pedodiversity analyzes, Ibáñez and Effland (2011) also suggest a new potential concept *Theory of Island Pedogeography*. Likewise SPARS seems to occur in soil microbial diversity communities (e.g., Ranjard et al., 2013).

Table 2 Richness, diversity, evenness, and dominance calculations: Pros and cons (after that Ibáñez et al., 1990).

	<i>Discriminant ability</i>	<i>Sensitivity to sample size</i>	<i>Richness, evenness or dominance</i>	<i>Calculation</i>	<i>Widely used</i>
α (log series)	Good	Low	Richness	Simple	Yes
λ (log normal)	Good	Moderate	Richness	Complex	No
Q statistic	Good	Low	Richness	Complex	No
S (species richness)	Good	High	Richness	Simple	Yes
Margalef index	Good	High	Richness	Simple	No
Shannon index	Moderate	Moderate	Richness	Intermediate	Yes
Brillouin index	Moderate	Moderate	Richness	Complex	No
McIntosh index	Good	Moderate	Richness	Intermediate	No
Simpson index	Moderate	Low	Dominance	Intermediate	Yes
Berger–Parker index	Poor	Low	Dominance	Simple	No
Shannon evenness	Poor	Moderate	Evenness	Simple	No
Brillouin evenness	Poor	Moderate	Evenness	Complex	No
McIntosh D index	Poor	Moderate	Dominance	Simple	No
Power law	Moderate	Moderate	Richness	Simple	No ^a
Z value					

^a Z value is the most used in taxa–area relations, but not as an abundance distribution model. Dominance is the opposite of rarity proposed by Whittaker in 1965 (see Magurran, 1988). Modified from Magurran AE (1988) *Ecological Diversity and Its Measurement*. London, UK: Croom Helm.

Fig. 2 Abundance distribution models. (A) Richness–area relationship by all countries using the FAO soil database; (B) a hypothetical distribution plot with the shapes of the most common abundance models; (C) ranked abundance list of pedotaxa for the Aegean archipelago showing a typical Hollow/Willi's curve. (A) Modified from Caniego J, Ibáñez JJ and San José Martínez F (2006) Selfsimilarity of pedotaxa distributions at planetary level: A multifractal approach. *Geoderma* 134: 306–317. doi: 10.1016/j.geoderma.2006.03.007, (B and C) modified from Ibáñez JJ, De-Alba S, Bermúdez FF and García-Álvarez A (1995) Pedodiversity: Concepts and measures *Catena* 24: 215–232, [https://doi.org/10.1016/0341-8162\(95\)00028-Q](https://doi.org/10.1016/0341-8162(95)00028-Q).

Abundance distribution models

Taxa abundance distribution models (ADM) use all the information gathered in a community. Taxa abundance data are described by families of distributions, whereas diversity is usually examined by four main models: geometric series, logarithmic series, lognormal distributions and MacArthur's broken stick model (Magurran, 1988). A rank/abundance plot or RAP (Fig. 2B) of the four models represents a progression ranging from the geometric and logarithmic series where a few taxa are dominant with the remainder fairly uncommon, through the lognormal distributions where species of intermediate abundance become more common and then to the conditions represented by the broken stick model in which empirical data show that species are more equally distributed (Magurran, 1988). Diversity experts display relative taxa abundance with taxa on the X-axis according to their decreasing abundance, while their relative abundance is shown on the Y-axis. Frequently, the same set of data might fit more than one ADM with (more or less) the same confidence levels, and it can be difficult to recognize which one is the "real" data distribution (e.g., Jiang, 2013). Although some ecological data fit other types of distribution, Magurran (1988) emphasizes that the four models mentioned should be used whenever possible to enable comparisons. Although the adjustment of abundance distributions rarely reaches the 95% significance level, this methodology aims to identify the best fit, with the goodness of fit of secondary importance.

Visual inspection of RAPs recommended by Mandelbrot, as well as the term “ht-index” (Jiang, 2013; Jiang and Yin 2014; Ibáñez et al., 2021) are useful for interpreting the results of a goodness of fit test. The RAPs in biological taxonomies and biodiversity inventories go back a century and are currently known as “Willis’s or Hollow curve,” which is also present in pedodiversity analysis based on pedological taxonomies (see Ibáñez and Bockheim, 2013; Ibáñez and Montanarella, 2013 for further details). The origin of this term comes from the concave shape of the frequency distribution of taxonomic assemblages when its taxa are ranked from the most to the least abundant (Fig. 2C). The Willis’s curve shows that there are many rare taxa within each assemblage and few very abundant taxa. The hollow curve distributions are well fitted by a power law or related statistical distribution models. In diversity algorithm terms this feature means that the evenness index (E) will not have the highest possible value, thus the Shannon entropy index (H) for a given number of species (S) never reaches its potential maximum value (all the taxa have an equiprobable number of individuals or cover).

Most data sets fit well with several models of distribution, for example, to both the lognormal and power-law distributions (Jiang, 2013; Ibáñez et al., 2021). This problem results from both sampling capacity and the statistical techniques. First, it is impossible to sample all taxonomic diversity in any sampling scheme because it is restricted in space and in time, which results in many “rare” or infrequent taxa not being sampled or identified. Consequently, the distribution model obtained will underestimate richness and overestimate evenness. Thus, the diversity figures are also affected. Similarly, the sample data could be fitted by a distribution model which might be different from what could be obtained with all the data from the study area (Tokeshi, 1993).

β diversity index

The β diversity measures the change in composition of taxa from one sampling area or habitat to another. The term was introduced by R.H. Whittaker in 1960 and is defined as “the extent of change in community composition, or degree of community differentiation, in relation to a complex-gradient of environment, or a pattern of environments.” In his seminal paper, Whittaker proposed several methods to measure β diversity. At its simplest, it could be defined as the ratio between gamma (regional) and alpha (local) diversities. The beta diversity quantifies numerically the number of different communities in the region. It not only considers the relation between local and regional diversity, but also informs about the degree of differentiation among pedological assemblages. A high β diversity index indicates a low level of similarity, while a low beta diversity index shows a high level of similarity. The simplest method proposed by Whittaker to quantify differences in diversity is the following

$$\beta = \gamma / \alpha \quad (4)$$

where gamma γ diversity is the total taxa diversity of a whole study area, and α diversity is the mean taxa diversity for each pedological assemblage. A pragmatic solution is to consider γ diversity as the total species diversity in the dataset and α diversity the mean species diversity per subunit. Over time diversity experts have continued to propose more mathematical expressions with varying degrees of complexity. As a result, there are now many procedures and β diversity algorithms proposed. Some of the oldest similarity coefficients are now being considered useful by diversity experts such as the Jaccard and Sørensen indices.

$$\text{Jaccard } J = j / (a + b - j) \quad (5)$$

and

$$\text{Sorensen} = 2j / (a + b) \quad (6)$$

where j is the number of taxa found at both sites, a is the number of taxa at Site A and b is the number of taxa at Site B. These indices are designed to equal “1” for complete similarity (that is where the two sets of taxa are the same) and “0” if the sites are dissimilar and have no taxa in common. These indices have the advantage of being simple. However, these coefficients do not take taxa abundance into account. Thus, all taxa have the same weight in the equation irrespective of their abundance (e.g., dominant, frequent, rare, etc.). This has led to similarity measures based on quantitative data (see Magurran, 1988).

For each assemblage of taxa, it is assumed that some taxa are replaced by others resulting from environmental or human factors. However, when these assemblages are of different sizes, it is possible that low abundance taxa could be nested subsets of the larger ones, as is proposed by the “nested subset theory” (see below). Therefore, the dissimilarity measured by β diversity could be due to substitution/replacement, nesting, human impact or all of them to a different degree. Thus, total dissimilarity can be portioned additively into replacement and nestedness components.

Ibáñez et al. (2019) note an important factor not previously taken into account in the literature: the design of the sampling areas. The authors split the soilscapes and vegetation of a given region according to two perspectives (i) drainage basins and (ii) bioclimates, and compared the results. For drainage basins, the driving force of β diversity in their study area was the nestedness, whereas for bioclimatic fragmentation it was the species replacement. The literature on Beta diversity is broad and can be analyzed from so many perspectives including numerical taxonomy and data analysis in general (see Feoli et al., 2013 in Ibáñez and Bockheim, 2013).

Diversity and the nested subset theory and taxa-range size distributions

Nested subsets theory

One of the other most common patterns detected in pedodiversity studies concerning SPARs is termed “nested subsets,” an idea proposed by Patterson and Atmar in (1986). Nestedness appears to be a near-universal property of the taxa assemblages studied by pedologists and ecologists provided that they meet certain conditions, such as belonging to geographic areas largely under similar environmental conditions allowing for β and γ diversity to be estimated. A fundamental asymmetry of ecological/pedological relationships is implied by nested subsets. This pattern arises in view of taxa that appear in smaller areas (e.g., islands or drainage basins of small size) and are also present in other larger ones of the same type. This does not, however, work both ways. In other words larger assemblages contain additional idiosyncratic pedotaxa that do not appear in the smaller ones (see Ibáñez and Bockheim, 2013 and Fig. 3A). Thus, less taxa-rich-assemblages tend to be subsets of more taxa-rich assemblages. The nested subset pattern arises because taxa differ in their distributions across heterogeneous spaces (usually with particular habitats), or imply locations with contrasting geographic histories. In pedological terms larger islands, on average, have more soil types than small ones because there is greater variety in soil forming factors, such as relief, climate and mature depositional landforms. This fact is the result of two driving forces: (i) there is a positive correlation (a power law) between the island size (or drainage basins) and relief/altitude that increases the environmental heterogeneity; (ii) larger islands and drainage basins have landforms that do not appear in the smaller ones (Ibáñez and Effland, 2011; Ibáñez et al., 2019). In pedological terms it is possible to predict the probability that some specific soil types appear according to the size of the above mentioned land units. Nested patterns have been documented for an abundance of pedological assemblages in more disparate habitats and on spatial scales, such as those induced by urban sprawl (see Zhang, 2013, in Ibáñez and Bockheim, 2013).

Fig. 3 Distribution matrix of pedotaxa for realistic (A) and perfect (B) nested matrices. Each horizontal and each row is organized from larger sites on top toward smaller sites at the bottom. Larger sites are expected to have greater richness in contrast to smaller sites. Each column represents the occurrence of a particular taxa, an unfilled box correspond to an absent taxa, most common taxa are expected to be present in all sites, while less abundant taxa are expected to be present at larger sites. There is a tendency for occurrences to cluster in the upper left corner of the table.

All nested patterns have a certain amount of noise. For hypothetically perfect nestedness (Fig. 3B), if a taxon is present in a given assemblage or island, it is also present in all larger islands with richer assemblages. If a taxon is absent from an assemblage, it is also absent from all smaller (i.e., less taxa-rich) assemblages. Taxa are ranked by number of occurrences among sampled habitats/sites; sampled habitats are ranked by taxa richness. The wedge-shaped pattern of occurrences in a taxa presence-absence matrix is characteristic of nested soilscape (Fig. 3B).

In a perfectly nested matrix (Fig. 3B) the hypothetical line that separates the occupied area of the matrix (i.e., the upper-left corner of the matrix) from the unoccupied portion is called the “boundary line.” Taxa absences above and to the left of the line are defined as unexpected absences, similarly to the taxa presented below and to the right that are defined as unexpected presences (Fig. 3A). When randomness is low, unexpected presences and absences cluster near the boundary line. In contrast, if randomness increases unexpectedness moves further away from it. The measurable “entropy” of the matrix is the result.

Several metrics have been devised to measure the fit of a given presence-absence matrix to the nested subset model (e.g., *Atmar and Patterson, 1995*). One metric is the “statistic T ,” which measures matrix disorder, entropy or temperature (*Atmar and Patterson, 1995*). This is calculated as the sum of squared deviations from the matrix boundary line (Fig. 3B) of unexpected presences and absences, divided by the maximum value possible for the matrix multiplied by 100. It also has the advantage of allowing for the identification of idiosyncratic taxa and sites. In other words, this procedure detects taxa or patches that contribute the most to matrix disorder by disrupting the nested pattern. The statistical significance of T is determined by comparing the index of the patterns with the random matrices generated through a Monte Carlo simulation.

Unexpectedness is similar to Boltzmann’s probabilistic description of entropy (disorder) and Shannon’s definition of information or surprise (e.g., the Shannon index). Unexpected presence or absence of taxa in island/drainage basins/habitats range from 0 °C in perfectly nested matrices to 100 °C in random matrices. Two forms of variability contribute to the temperature of a matrix: (i) the random variation of environmental stochasticity and (ii) the “coherent” variability caused by specific (bio)-pedogeographic events. Random events create a uniform gray “noise” band along the length of the boundary line. In contrast, coherent events generate idiosyncratic spikes in taxa or island entropies that are more random than the ones for the overall matrix. Random noise generates a break in the smoothness of the boundary line. The less smooth this line is, the more unexplained variety occurs in the matrix (*Atmar and Patterson, 1995*).

The ubiquity of nested subsets in soilscape analysis refutes the notion that this pattern is the result of idiosyncratic properties in biologic communities (see *Ibáñez et al., 2021*); additional mathematical information is provided by *Atmar and Patterson (1995)*.

Taxa-range size distributions

Other patterns usually detected in pedodiversity and biodiversity are termed “taxa-range size distributions,” which indicates that widespread taxa are much more abundant than taxa of restricted occurrence in a territory (see *Ibáñez and Bockheim, 2013* and references therein). Once again, a power law describes this pattern: the relationship between the abundance and their geographic range.

Diversity, fractals and multifractals

Diversity, fractals and multifractal: What are the relationships?

Power laws are the only decreasing monotonic functions that do not vary with changes of scale; they are, therefore, known as “free scaling laws” (see below). Thus, it is not surprising that some time ago many scientists started to analyze the relations between power laws and fractals (see San José and Caniego, 2013 in *Ibáñez and Bockheim, 2013*). According to many authors, biodiversity, pedodiversity and the species-area and pedotaxa-area relations are fractal and or multifractal structures (see San José and Caniego, 2013 in *Ibáñez and Bockheim 2013*).

As the mathematical explanation of fractals and multifractals is complex and extensive, we describe only the most basic concepts, specifically, those related with diversity analysis, as explained by *Caniego et al. (2006)*. For many fractal and multifractal experts, the detection of power laws (which, is not a trivial problem) is proof of the existence of underlying fractal processes or structures. If this is the case, the estimates of diversity (at least in those cases where the data sets agree with power laws) would be a manifestation of the nature of underlying fractal structures (e.g., floristic assemblages of phytocenoses, biotaxonomic schemes, soil classifications, phylogeny and habitat diversity, etc.). San José and Caniego (2013, in *Ibáñez and Bockheim, 2013*) detected fractal and multifractal patterns in pedodiversity studies (see below). There are two main approaches in multifractal analysis: (i) singularity exponents and (ii) Rényi dimensions. The Rényi spectrum of generalized dimensions summarizes some important diversity indices that are widely used in diversity analysis (*Borda-de-Água et al., 2002*).

It is remarkable that in the sphere of applied physics, relations between statistical and information entropies (e.g., Shannon Index), and fractals have also been detected, especially in developments on multifractal analysis. The most important concepts of fractal dimension are the Kolmogorov capacity D_C , the Hausdorff-dimension D_H , the correlation dimension D_{corr} , and information dimension D_I .

The different fractal dimensions mentioned above D_H , D_{corr} , D_I and D_C are not equal, but satisfy the inequality:

$$D_{corr} \leq D_I \leq D_H \leq D_C \quad (7)$$

where equality occurs if and only if the fractal is strictly self-similar and homogeneous. Since the inequality is quite tight in most cases, in most applications it is tacitly assumed that $D_{\text{corr}} = D_H$ mainly because the numerical determination of D_{corr} is much easier than that of D_H .

Diversity, fractals and multifractals in soil sciences

Power-law scaling of pedomorichness–area relationships was first conjectured by Ibáñez and De Alba in 2000 (see Ibáñez and Bockheim, 2013) for Earth soil systems and they have been reported later for different soil landscapes, pedological classifications, soil map standards and soil geography studies (see Ibáñez et al., 2021). For example, the spatial distribution of pedotaxa at a planetary and continental level or by biomes also conforms to fractal and multifractal structures. Likewise, they have been interpreted in terms of the self-similarity of the spatial distribution of pedomorichness (Caniego et al., 2006). Thus, the power law becomes the by-product of a fractal structure while the scaling exponent quantifies the regularity trend in the reproduction of the spatial pattern of pedomorichness within a certain range of scales. It is noticeable that the same occurs concerning the structure of pedological and biological classifications (e.g., see Ibáñez and Montanarella, 2013 and references therein), but also multifractal analysis can also explain diversity indices, and how they can be interpreted as pedodiversity indicators.

Caniego et al. in 2006 (see San José and Caniego chapter in Ibáñez and Bockheim, 2013) computed Rényi generalized dimensions for the abundance distribution of pedotaxa for the Earth's five landmasses and the whole world using the FAO Soil Database at the second level (FAO, 1974). Their results indicate that the complex behavior of pedodiversity distributions at the planetary scale follows a well-defined multifractal behavior (see San José and Caniego in Ibáñez and Bockheim, 2013). Therefore, multifractal parameters can be used as pedodiversity indicators and show promise for analyzing and characterizing the complexity of soil development at multiple scales. Thus, multifractal analysis could be a way to unify a framework that includes the common procedures to characterize diversity: taxa-abundance distributions, taxa–area relationships, nestedness, and diversity indices (e.g., Richness, Shannon Entropy, Shannon Equitability, Simpson Index, Berger–Parker Index) (Caniego et al., 2006), as can be seen below.

Power laws, fractal and multifractal structures also appear in the soil matrix and soil living communities (see Ibáñez, 2017 and references therein). A well-developed soil matrix structure is a self-structured or self-organized habitat with very specific and fascinating properties. Three examples will suffice to understand these features. The inorganic particles that form the soil matrix (excluding rock fragments) constitute what is called texture, consisting of particles of decreasing size: sand, silt and clay. These small particles interact and bind with particles of decomposing organic matter (that includes different types of material with particular properties) forming so-called soil aggregates (e.g., Guadagnini et al., 2013). The latter confer on the soil their most relevant properties needed to sustain life, water and air circulation, as well as regulation of the pedoclimate. It seems that both the size distribution of the soil particles as well as the aggregates and soil pores conform, more or less, to the same statistical number–size distribution previously detected in pedodiversity analysis. These are power laws, fractals or multifractals where there are far more small soil particles, aggregates, and pores and organisms than large ones (e.g., Guadagnini et al., 2013).

Similarly, the formation of most soils implies that the rocks and sediments become structured (self-organized) (e.g., see Phillips, 2017) in layers or horizons, with different chemical and physical properties, leading to the creation and increase in the number of habitats that can be inhabited by idiosyncratic assemblages of soil organisms (e.g., Crawford et al., 2012 and references therein). In other words, the increase in the number of soil horizons according to pedogenetic progress in many pedotaxa entails the genesis of new and different habitats, and as a result, the increase in self-organized soil biodiversity, since it begins to form from fresh rocks or parent materials. Furthermore, soil structures produce an abundance of microhabitats (e.g., Nunan et al., 2003, among many others). Therefore, the soil should be considered to be a cascade of nested habitats within each other, with the creation of different macro-, meso- and micro-environments with different biological communities (soilscapes, soil bodies, soil horizons, soil architecture, soil aggregates, etc.) (e.g., Nunan et al., 2003).

Various experts have shown evidence that both soil bodies and soilscapes are complex systems (e.g., Phillips, 2017; San José-Martínez and Caniego, 2013 in Ibáñez and Bockheim, 2013) and that they show fractal properties. In fact, Jonathan Phillips demonstrated that Hans Jenny's factors of soil formation respond as non-linear systems. We assume that such a link occurs between fractals and complex systems and also occur for the whole of the Earth surface system (e.g., Phillips, 2016).

Diversity analysis and the Willis curve

The broad universe of the Willis curve distributions

In previous sections we have tried to synthesize the studies carried out in the analysis of pedodiversity and its relationships with those obtained in the science of biodiversity. More recently, two meta-analyses have been published that may reveal some intriguing aspects not previously taken into account in such inquiries (Ibáñez et al., 2021).

The opportunities offered by geospatial technologies in recent decades have resulted in certain controversies in the geographical thinking and classical analysis of spatial structures. One of these involves the ubiquity of scaling laws such as power laws and fractals (Mandelbrot, 1982), as we have seen in previous sections. A simple and well-known metaphor for the spatial fragmentation of the polygons in a map (Jiang, 2015 in Ibáñez et al., 2021) is the following: “if we forcefully throw a glass bottle to the ground, it will fragment into pieces of all sizes with the abundance of any size class decreasing as the size increases, and this relationship between size and abundance will follow a power law.” There are many claims in geographical sciences suggesting that the classical

geographical analyzes and map representations are not appropriate in the analysis of geographical spaces. A paradigm shift has been proposed from our current Gaussian thinking to another, based on Paretian thinking, as has happened with other scientific disciplines (Ibáñez et al., 2021 and references therein).

Normal distributions and the Gauss curves and related current quantitative methods are commonly used in statistical analysis. However, the growing ubiquity of power laws signifies that Pareto rank/frequency distributions, fractals, and underlying scale-free theories are increasingly widespread and provide valid characterizations of natural and social structures and their dynamics. This is because data extremes of the distribution should be considered not the Gaussian statistical averages. Although it is possible that both modes of thinking are relevant (see below).

Geographical analyzes show the ubiquity of Pareto power-law distributions over Gaussian bell curves and linear fits. These well-established laws correspond more or less to the more general concept of the Willis curve or long tailed distributions. Therefore, a new type of statistical analysis that includes Bayesian thinking is needed by researchers in disparate disciplines. Within this framework, the general notion that there are far more small things than large ones across several orders of magnitude should be considered in geographical and mapping analyzes (Jiang, 2015 in Ibáñez et al., 2021), as this has been demonstrated to be the rule or conjectured as a “universal law” (Salingaros and West, 1999; in Jiang, 2013; Jiang and Yin, 2014).

In the most problematic cases, the dataset might fall into the Willis curves category. This occurs for a variety of potential reasons (small data sets, small uncertainties in data quality, etc.). This is the main reason that controversies have arisen in some studies regarding whether a given geographical feature should be considered as fractal or not. Jiang (2013) claims that the geographical space is dynamic and is changing over time. Therefore, sometimes the structures could trend toward fractals even when they do not reach their full development. Ibáñez et al. (2021) show many examples of this in the most disparate disciplines, scientific, social or economics among others (e.g., urban maps). When these circumstances, among others, occur, tested datasets might fit better with other related distributions, such as geometric, logarithmic, lognormal or exponential functions rather than a power function (Jiang, 2013). In general, power laws and fractals are linked to non-linear and or complex systems in which heterogeneity/diversity and the interaction/connectivity between their constituent elements is required (Ibáñez et al., 2021 and references therein). Therefore the Jiang (2013) conjecture seems to be corroborated beyond cartographic representations across the most disparate disciplines and scales.

Willis curve and long tailed distributions. The example of soil mapping

A map series is a set of maps that generally follow the same standards and cover an area or a country in a systematic way. The maps of a given series have the same scale, format and system of symbolization (graphic semiology). National map agencies in each country commonly have sets of map series (for example, topographic series) at different scales, based on their larger scale maps, and proceeding to smaller scale maps through processes of scale reduction and generalization. Map generalization is a very complex visual-intellectual process. Robinson (1995, in Ibáñez et al., 2021) defines the whole process in terms of four aspects: simplification, classification, symbolization and induction. When reviewing different areas of cartography, we found no reference related to fractal structures or statistical formulae that guide the content and production of maps (e.g., Ibáñez and Montanarella, 2013).

Scaling hierarchies and the ht-index

Jiang (2013) propose the “ht-index,” complementary to fractal dimension, to better understand geographic patterns, which analyzes and quantifies the texture of the Willis curves and the fractal or scaling patterns detected in geographical spaces. According to Jiang (2013), many controversies over whether a given structure is fractal or not, occurs as a result of the narrow and “orthodox definition” of fractal dimension as a measure or index for characterizing free scaling features or forms.

Jiang and co-workers proposed and tested, in different publications, a very simple but useful mathematical procedure that attempts to capture the free scaling/fractal nature of spatial structures using Willis curves or Rank Abundance Plots (RAPs), as shown in Fig. 2C. According to Jiang’s conjecture (“there are more small things than large ones”), when a structure is analyzed at different “scales,” in the sense of the latter concept being applied in fractal sciences, it is possible that the measurement of the complexity and coherency of Willis distributions, considered by these authors as fractals, correspond with their proposition of a relaxed definition of fractal (fractal complexity). These authors state that “the ht-index captures how many scales, ranging from the smallest to the largest, form a much greater number of small things in the scaling hierarchy. The ht-index is defined as one plus the recurring times of small things than large ones. In other words, a geographic feature has an ht-index of h if the pattern of far more small things than large ones recurs $(h-1)$ times at different scales. The higher the ht-index, the more complex the geographic feature.” Therefore given an RAP curve, it is easy to deliver a type of “scaling hierarchy” using the ht-index.

An RAP is the first step in obtaining an ht-index. Then the same analysis is performed once again for those data (objects) that are above the arithmetic mean of the dataset analyzed, to differentiate between small (termed “the tail”) and large (called the “head”) objects. Note that this subset is considered a nested RAP of the former RAP. If the result is “more small things than large ones” the same operation is repeated recursively until the condition is violated. The number of times that the “more small than large” pattern occurs (“scaling hierarchy”) is a measure of the complexity of the full data RAP, as a nested hierarchy or scaling. Jiang and coworkers have developed more quantitative versions of the method to estimate the ht-index. Ibáñez et al. (2021) corroborate Jiang’s proposal in pedodiversity studies. Jiang’s proposal is also applicable in non-geographic analyzes, as we have seen previously.

The logarithmic thinking: Cognition soil maps and soil taxonomies

According to some anthropologists, some aboriginal cultures (e.g., the Mundurucu indigenous peoples of the Amazon) calculate logarithmically instead of in the linear way, which is typical of western culture. Likewise experimental psychologists have shown evidence that childrens' minds begin to calculate logarithmically, changing over time and gradually (probably through cultural training) to do so in a linear way (see bibliography in Ibáñez et al., 2021). Why do we perceive the world around us logarithmically? According to some authors, it is that such a way of calculating is an adaptive advantage in the search of natural resources in contrast with Gaussian thinking.

Does the mind work logarithmically? Both biology and biological taxonomies conform to free scaling laws (see Ibáñez and Montanarella, 2013 and references therein). Soil and biological classifications were developed independently across decades and considered as natural biological taxonomies and artificial soil taxonomic constructs (Ibáñez and Montanarella, 2013). None of the developers of these taxonomies made intentional use of logarithmic thinking. Rather, soil taxonomies were intuitive/rational products of numerous groups of experts working independently over decades in different disciplines, and without considering the mathematical aspects that might be desirable to create efficient taxonomic structures. The same can be said of cartographic products and their rules for making maps, yet power laws again appear to be ubiquitous in their official standard structures (e.g., Soil Survey Staff, in all versions) as well as in the resulting structures derived from them (Ibáñez et al., 2009).

The case of fractal coupling between the soil taxonomies, soil survey and mapping procedures will serve as an example that corroborates the above mentioned theses. Some studies show that the USDA (United States Department of Agriculture) Soil Taxonomy has the same mathematical structure as some biological ones which conform to physical laws that dictate and optimize information flow in user-friendly retrieval systems according to the Jaynes' (maximum entropy) Principle (see Ibáñez and Montanarella, 2013). Likewise Ibáñez et al. (2009) demonstrate that the fractal or multifractal nature of the USDA Soil Taxonomy is strongly linked with conventional soil survey practices. In fact, most surveys are packed with power-law distributions, such as: (i) hierarchic taxonomic level used according to the map scale; (ii) minimum polygon size fits the functions to the map scale; and (iii) boundary density-scale map relationship, among others (see Ibáñez et al., 2009 and references therein). These results supported Beckett and Bie (1978), who showed that most pedological maps have attributes that conform to a power law or other related long tailed statistical distribution. Consequently, a cascade of power laws occurs in soil survey products and soil taxonomies (see Ibáñez and Montanarella, 2013 and references therein). As both activities are strongly linked, it seems as if the minds of soil surveyors and soil taxonomists create similar fractal structures. This process could be the reason for why maps devoid of legends and other information have a strong resemblance and information content, and without scales they provide a clear fractal signature. The same is true concerning the hierarchical branching of classical taxonomies. Experts in cartography know, more or less, well the rules that they apply. However, in the bibliographic material consulted, there were no references about the implications of human cognitive bias in their practice, or to mathematical relationships between classifications and map scale.

Therefore, it remains to be clarified whether Paretian and Gaussian thinking (i) exist simultaneously in our minds; (ii) if Paretian thought is a residual product in our cultural evolution, and replaced by Gaussian thinking in our civilizations over time; (iii) if we unconsciously project our logarithmic mental maps onto nature and structure the world around us in such a way that many scientific findings are more a mental product than an unchanging reality; and (iv) if our minds and the world around us and with which we interact are inescapably the product of a fractal universe (Ibáñez et al., 2021).

In summary, the systems used by soil surveyors and soil taxonomists as a whole have fractal-like structures. Our view is that the standards of many natural resource maps are similar, therefore, it could be conjectured that scale-invariant information processing is intuitive to human minds and that a more rigorous formalization of survey-taxonomy architectures may help practitioners to understand better their activities and constructs, and provide a way to improve them.

Summary

In broad terms, pedodiversity is the study of the variety of soil types within an area using mathematical tools taken from biodiversity. The most common tools used in pedodiversity are related with the measurement of richness (amount of soil taxa in a region), abundance (sum of soil types) and evenness (or the relative distribution of soil individuals). One of the most relevant findings obtained in pedodiversity analysis is that the patterns and regularities are the same for ecological and pedological entities, and possibly for many natural and artificial resources (e.g., geodiversity, land system units). This means that the tools applied in diversity studies have been found to be useful for other purposes (taxonomic structures, standards for soil surveys and maps studies, etc.) that transcend their initial objectives. Pedodiversity mathematical tools were described, as well as other mathematical approaches of relevance that include: nested subset analysis, species-range size relationships, fractals and multifractals and non-linear dynamics.

It is intriguing that the regularities previously detected in biodiversity studies were later corroborated in the study of other entities not typically considered living beings (see Ibáñez et al., 2021). However, it seems even more disconcerting that they emerge again in the analysis of structures made by human minds (e.g., pedological and biological hierarchical taxonomies, soil and vegetation mapping).

Abstract

Soil development models exist at the pedon scale and the landscape scale. Both groups of models have developed along different pathways, and still differ in the processes covered, state of testing and application domain. An overview of different models indicates that their application domains are converging to simulation of global change scenarios. Prerequisites are that these soil(-scape) models take climate and land use change as input at their upper model boundary, and that they allow the simulation of soil hydrology.

Glossary

Accuracy The degree of conformation of a (simulated) property to the measured reality.

Boundary condition Input at the boundary of the modeled soil system, either varying over time at the top (soil–atmosphere interface) and the bottom (e.g., bedrock) or at time zero (initial situation).

Pedon A three-dimensional soil body that is near 1 m² at the surface and extends to the bottom of the soil. In a pedon modeling context, lateral variation is usually neglected and focus is on the (development of) vertical variation.

Soilscape A three-dimensional soil body of undefined area and extending to the bottom of the soil, the saprolite or the bedrock. Lateral variation and its development are, at least at the soil surface, studied explicitly and there is also a focus on the (development of) vertical variation.

Key points

- Soil development models exist at both landscape and pedon scales and have different development histories.
- Pedon models contain mechanistic process formulations of water, solute and heat flow and include various biological, chemical, and physical processes to quantify sources and sinks.
- Soilscape models contain mechanistic formulations of surface mass redistribution processes and functional formulations of water flow and include various biological, chemical and physical processes in a quantified but empirical way.
- Soil(-scape) model inputs at the soil–atmosphere interface can be obtained by proxy-based reconstruction, by outputs from earth system models and by definition.
- Model testing is at present more commonly applied with pedon models than with soilscape models.
- Both types of model allow the analysis of global change scenarios in terms of soil development (including soil organic carbon) if as minimum they include water flow.

Introduction

The term “soil development” is used to cover the change of soil over time in terms of its horizons and its properties. Traditionally, soil development research reconstructs the pathway from a parent material to an observed depth distribution of the biologically active zone (A-horizons), zones of export (E-horizon) and of accumulation (B-horizon) of soil components and zones of weathering (regolith). Essentially, the (often uncertain) initial status, the measured (certain) current status of the soil and process knowledge are used to hypothesize about this pathway, aided by a wide range of techniques (e.g., mineralogical analyzes, microscopy, chemical analyzes, etc.) to estimate soil properties (e.g., mineralogy, proof of biological activity, pedogenic oxides, etc.). The well-known factorial model by Jenny (1941, 1961), based on work by Dokuchaev (1886) and Hilgard (1906) (all in Minasny et al., 2015) was a first attempt towards a quantitative, functional linkage between the soil that has formed and climate, organisms, relief, parent material and time: CLORPT.

From, roughly, the 1980s onwards this changed (Fig. 1) by quantification of the dynamics of soil processes in a mechanistic sense, in the context of research on (a.o.) fate of pesticides (Wagenet and Hutson, 1986), acidification (De Vries et al., 1994) and eutrophication (Hansen et al., 1991). The focus was on short (decadal scale) temporal extents and the ambition to allow prediction into the future. This trend is still ongoing, currently often in the context of global change research. Knowledge obtained and its various implementations have been fed back into the community of soil development researchers. One of the reasons is that global change is directly linked to the factors of soil formation climate, organisms (including human activity), and indirectly linked to relief and parent material as well. In the narrower context of modeling soil development, model development itself has followed two tracks: the landscape/soilscape track and the pedon (1-D) track (Fig. 1).

Here, we will focus on how today's soil development models are organized, what system they describe and how they link to the wider environment via boundary conditions. The landscape–soilscape models and the pedon models will be described separately as they have different origins and underlying concepts, and do not produce the same output variables. As a consequence, interpretation of the model outputs towards soil horizonation differs between these models.

Current soil-landscape modeling approaches

Focus on pedon

Kirkby and Hoosbeek and Bryant were among the first (Minasny et al., 2015) to develop process-based formulations of chemical reactions and weathering of minerals at the pedon scale and coupling these with a water and solute flow model. This allowed the development of weathering profiles and podzols to be mimicked. Others followed (Fig. 1) but it would take until the 21st century to build mechanistic models that describe more aspects of profile development such as the formation of A, E and Bt horizons by the interaction of processes of bioturbation, decalcification, clay dispersion and transport (Finke, 2012).

Fig. 2 depicts a pedon-scale soil development model. The soil profile is commonly schematized in compartments (finite difference approach), though also a finite element schematization is possible. Flow of water, heat and (dissolved or dispersed) matter between the compartments is commonly simulated by numerically solving partial differential equations (PDE) that combine flow equations with mass balance equations. The mass balance includes source/sink terms by the production or depletion of stocks. In case the soil compartments are considered a continuum of soil, water and air, the Richards equation for water flow in variably saturated soils is a well-known example of such PDEs. More advanced methods exist that take into account soil structure (e.g., macroporosity) explicitly, and simpler methods (e.g., capacity or bucket models) also exist.

For soil development models, additional modes of mass transport need to be considered such as bioturbation, plowing, cryoturbation, etc. This can be done either as a separate mass transport process or as a diffusion term in the PDE (Keyvanshokouhi et al., 2019).

As soil development models may cover millennia, transport-related properties (e.g., hydraulic and thermal conductivity) and capacities (e.g., water retention, heat capacity) cannot be considered constants. The changing stocks in a soil compartment (e.g., contents of clay, carbon, minerals, elements in various pools) (Fig. 3) can be used to feed pedotransfer functions (Link to Encyclopedia Chapter on PTFs here) to update these transport-related properties.

These pedon-scale models, essentially enhanced leaching models, need quantitative descriptions of the conditions to be met at the system boundaries, both in a temporal and in a spatial sense. This makes them responsive to the factors of soil formation that operate at the system boundaries over time T (Figs. 2 and 3): At $T = 0$, Parent material = texture + unweathered phase; along the timeline Climate = $P + PE + T$, Organisms = vegetation + bioturbation + tillage + cropping + fertilization. Pedon models, in essence, describe the vertical transport of matter, so surface mass redistribution processes are not represented and erosion and deposition are effectively also boundary conditions.

The outputs of pedon models are time-varying depth distributions of various soil properties. These still have to be converted to horizons if that is required. As an example, Finke et al. (2013) developed rules, for a Belgian loess soil that post-process time–depth patterns of contents of organic carbon, clay and calcite to time–depth patterns of A, E, Bt and C-horizons.

Strong points of pedon models at present are:

1. A fairly strong process coverage (Minasny et al., 2015), allowing simulation of the formation of various soil types;
